ABSTRACT

Regulatory pathways that drive early hematogenous dissemination of tumor cells (DTC) in the bone marrow to define patients with early disseminated breast cancer and identified low retinoic acid-induced 2 (RAI2) expression to be significantly associated with DTC status. Low RAI2 expression was also shown to be an independent poor prognostic factor in 10 different cancer datasets. Depletion of RAI2 protein in luminal breast cancer cell lines resulted in dedifferentiation marked by downregulation of ERα, FOXA1, and GATA3, together with increased invasiveness and activation of AKT signaling. Functional analysis of the previously uncharacterized RAI2 protein revealed molecular interaction with CtBP transcriptional regulators and an overlapping function in controlling the expression of a number of key target genes involved in breast cancer. These results suggest that RAI2 is a new metastasis-associated protein that sustains differentiation of luminal breast epithelial cells.

SIGNIFICANCE: We identified downregulation of RAI2 as a novel metastasis-associated genetic alteration especially associated with early occurring bone metastasis in ERα-positive breast tumors. We specified the role of the RAI2 protein to function as a transcriptional regulator that controls the expression of several key regulators of breast epithelial integrity and cancer. INTRODUCTION

In most patients with cancer, mortality is linked to metastasis. To prevent the occurrence of metastasis, different chemotherapeutic agents with severe side effects are currently administered systemically. However, many patients relapse after chemotherapy, most likely due to the activation of dormant disseminated tumor cells (DTC), which are non-proliferating and resistant to conventional chemotherapy (1). Using sensitive immunocytochemical assays, it has been shown that bone marrow is a common homing organ for DTCs of different origins, including breast, lung, and colon carcinomas (2–4). Several studies, including a large-scale pooled analysis (5), have shown that the presence of even a single DTC in the bone marrow of patients with breast cancer is an independent prognostic factor (3, 5).

Most cancer types are thought to be initiated and progress in a similar manner and share a common set of characteristics often called “the hallmarks of cancer,” which include genome instability and mutations. Also, a strong correlation between hematogenous dissemination and early clinical diagnosis has been established (6). In addition, several wide-ranging studies of expression profiling have shown positive correlation between the expression of the luminal markers ERα (ESR1), GATA binding protein 3 (GATA3), and forkhead box protein A1 (FOXA1) and well-differentiated breast tumors, and favorable clinical outcome (7, 8).

Thus far, activation/inactivation of several important oncogenes and tumor-suppressor genes (TSG), such as HER2, EGFR, and TP53, have been described as driving breast cancer development and progression (9). For the dissemination and outgrowth of metastases, another set of metastasis-suppressor genes (MSG) and activator genes are required. These MSGs, in contrast with classic TSGs, are less well characterized and appear to be more cancer type–specific and rarely inactivated by mutations (10, 11). Notably, the time at which individual cells begin to spread from a primary tumor mass is unclear, and regulatory pathways that control early hematogenous dissemination into the bone marrow remain insufficiently defined (1).
In this study, we identified retinoic acid–induced 2 (RAI2) as a putative suppressor of early hematogenous dissemination of tumor cells to the bone marrow. RAI2 was initially described as a retinoic acid–inducible gene but its specific function has not yet been determined even though it has been assumed to play a role in development (12). Here, we show that depletion of RAI2 expression in luminal breast cancer cells is associated with a loss of epithelial differentiation, which leads to an aggressive tumor phenotype and increased invasiveness. Our findings indicate that early hematogenous dissemination of tumor cells, particularly in hormone receptor–positive breast cancer, is mediated by RAI2.

**RESULTS**

**Gene Expression Profiling and DTC Signature**

The gene signatures of 32 breast tumor samples were assessed, and 31 were classified as luminal A (n = 16) or B (n = 15) tumors, which correlated with the positive hormone receptor status of the tumors as determined by immunohistochemistry (Supplementary Table S1). This homogenous group of early-stage tumors was further divided into two subgroups based on DTC status, and the rank-sum test was used to identify genes that were associated with DTC status. After correcting for multiple testing, 28 genes corresponding to 54 Ensembl transcripts were found to be significantly downregulated, and only four transcripts were significantly upregulated in DTC-positive breast cancer samples, indicating a prominent role for potential suppressors of early dissemination (Fig. 1 and Supplementary Table S2). The genes characterizing the DTC signature are located on 17 different chromosomes without any clustering to specific regions or common chromosomal break points. We used the significant genes for clustering analysis with a large publicly available dataset (GSE3494). Interestingly, most of the downregulated genes were, in this dataset, downregulated in the basal and/or HER2-positive type of breast tumors and clustered as well with TP53 mutants, high grade, and proliferation (Fig. 1). The results indicate that our DTC signature obtained from patients with luminal breast cancer defines a more aggressive dedifferentiated tumor population within the luminal group usually found among basal and HER2-positive patients. The original results were not biased by an uneven distribution of grade, Ki67, or mutant p53 status of the study cohort (Supplementary Table S1).

**Figure 1.** Clustering analysis of DTC-associated genes. Heatmap of the 32 significant genes from the initial DTC analysis in 251 breast tumors, with genes and samples clustered separately. The color coding at the top indicates the breast cancer subtype. Below the heatmap, phenotypes are encoded such that black indicates a poorer value in terms of outlook. ER, estrogen receptor α; PgR, progesterone receptor.
RAI2 Is Downregulated in Early Metastasized Breast Tumors

RESEARCH ARTICLE

To provide further evidence of the prognostic impact of DTC-associated genes, we performed in silico validation of all significant genes using six publicly available breast datasets comprising a total of 3,613 breast cancer patients (Supplementary Table S3). The prognostic relevance of RAI2 was also verified in two lung cancer patient cohorts as well as one colon and one ovarian cancer patient cohort (Supplementary Fig. S1). Using appropriately preprocessed gene expression values, samples in the datasets were separated into high-expression and low-expression groups using the extreme quartiles. Differences in overall survival (OS) or disease-free survival (DFS), depending on data availability, between these groups were determined by the Kaplan–Meier estimates of survival and the log-rank test. A total of 27 genes showed a significant association in at least one dataset, whereas 16 genes showed an association in at least two datasets. Low RLN2 and RERG expression was significantly associated with shortened survival in four of the six breast datasets (Supplementary Fig. S2), whereas lower RAI2 transcript expression was associated with shortened survival in all six tested breast cancer datasets (Fig. 2) as well as in all the other lung, ovarian, and colon cancer datasets (Supplementary Fig. S1). Among the four upregulated genes, high ABHD12 expression was associated with worse survival in two datasets.

Figure 2. Validation of RAI2 as a prognostic marker. Survival analysis using the extreme quartiles of RAI2 mRNA expression. RAI2 mRNA expression was determined in six published breast cancer datasets [for details, see Table S3] and analyzed using the Kaplan–Meier estimations. P values were calculated on the basis of the log-rank test.

Prognostic Impact of the DTC-Associated Genes

To provide further evidence of the prognostic impact of DTC-associated genes, we performed in silico validation of all significant genes using six publicly available breast datasets comprising a total of 3,613 breast cancer patients (Supplementary Table S3). The prognostic relevance of RAI2 was also verified in two lung cancer patient cohorts as well as one colon and one ovarian cancer patient cohort (Supplementary Fig. S1). Using appropriately preprocessed gene expression values, samples in the datasets were separated into high-expression and low-expression groups using the extreme quartiles. Differences in overall survival (OS) or disease-free survival (DFS), depending on data availability, between these groups were determined by the Kaplan–Meier estimates of survival and the log-rank test. A total of 27 genes showed a significant association in at least one dataset, whereas 16 genes showed an association in at least two datasets. Low RLN2 and RERG expression was significantly associated with shortened survival in four of the six breast datasets (Supplementary Fig. S2), whereas lower RAI2 transcript expression was associated with shortened survival in all six tested breast cancer datasets (Fig. 2) as well as in all the other lung, ovarian, and colon cancer datasets (Supplementary Fig. S1). Among the four upregulated genes, high ABHD12 expression was associated with worse survival in two datasets.

Quantitative Real-Time RT-PCR Verification of RAI2 Expression

Because RAI2 downregulation was significantly associated with both positive DTC status and poor OS, it was chosen as a candidate gene for further validation and functional tests. The expression of RAI2 was tested in 76 mainly hormone receptor-positive primary tumor samples from 36 DTC-positive and 40 DTC-negative cases. We could validate that RAI2 mRNA expression was significantly downregulated in DTC-positive patients (P < 0.05; Supplementary Fig. S3A). These results provide evidence that significantly lower RAI2 gene expression is associated with an aggressive tumor phenotype and underlies the putative role of the RAI2 protein in the suppression of early tumor cell dissemination.

Prognostic Impact of RAI2 Expression

Multivariate Cox proportional hazards model analysis of the six different breast cancer datasets showed that RAI2 gene expression provides survival information independent of other prognostic factors, making this gene interesting for further validation and functional tests (Fig. 2 and Supplementary Table S4). Additional survival and clinical correlation analyses were performed for RAI2 using the large METABRIC breast cancer dataset (13) EGAS00000000083.
Figure 3. Analysis of RAI2 mRNA and protein expression in human breast cancer tissue and cell lines. A, RAI2 mRNA expression was determined in a large published expression dataset breast #6 (13) and correlated with the indicated clinicopathologic parameters. RAI2 mRNA expression according to ERα status, histologic grade, and breast carcinoma molecular subtype is shown. B, survival analysis in extreme quartiles of RAI2 expression in ER+ and ER- patients. RAI2 expression was determined in the dataset breast #6 and analyzed in the Kaplan–Meier estimations. P values are calculated on the basis of log-rank tests. C, RAI2 and ERα protein expression in a panel of human breast carcinoma cell lines was determined by Western blot analysis using two polyclonal RAI2-specific antibodies that recognize either a C-terminal or internal epitope. Equal loading was demonstrated using an antibody recognizing HSC70 protein. D, determination of RAI2 protein localization in the luminal breast cancer cell lines MCF-7 and CAMA-1 by immunofluorescence staining (blue, DAPI/DNA staining; green, α-RAI2). E, Western blot analysis of RAI2 protein expression in whole-cell extracts of the indicated cell lines following either hormone depletion or treatment with ATRA or ICI182,780 (ICI) for 5 days.

comprising 1,992 patients (Fig. 3A and Supplementary Fig. S3B). A highly significant correlation between RAI2 mRNA expression and ERα status and the molecular luminal A subtype (both P < 0.001) was found, which is particularly associated with well-differentiated tumors and good clinical outcome. Furthermore, a statistically significant correlation between decreased RAI2 mRNA expression and differentiation grade, mutant TP53, and advanced stage was found (all P < 0.001), whereas no association was found to lymph node status. A strong association with hormone receptor status was furthermore detected in 12 other datasets using the Oncomine platform. In each dataset, a significant correlation could be found between high RAI2 status and hormone receptor-positive status (Supplementary Fig. S4).
To test whether the prognostic power of RAI2 expression in breast cancer is due to its association with ERα status, we carried out a survival analysis of the large dataset (13) grouping the patients according to ERα. RAI2 status showed that the worst survival was found for patients with low RAI2 expressers and an ERα-negative status followed by RAI2-low/ERα-positive patients, indicating a stronger impact of RAI2 than ERα status with regards to poor patient outcome (Fig. 3B). These results indicate that low RAI2 mRNA expression is associated with less differentiated and more aggressive breast tumors, especially in the ERα-positive patient cohort.

Expression of RAI2 Protein in Breast Cancer Cell Lines

To further investigate the biologic relevance of RAI2 expression in breast cancer, we evaluated RAI2 expression at the protein level in a panel of breast cancer cell lines (Fig. 3C). Western blot analyses indicated that RAI2 protein was generally expressed in all tested breast cancer cell lines; however, a correlation between cancer subtype of cell lines and intensity of RAI2 protein expression was found. As in the patient data, we found that the RAI2 protein was most abundantly expressed in cell lines corresponding to the luminal ERα-positive subtype, whereas RAI2 protein expression was considerably lower in HER2-overexpressing and highly aggressive basal cell lines. The immortalized, nontransformed breast epithelial cell line MCF-10A showed the highest RAI2 protein expression. Immunofluorescence analyses demonstrated a speckled intranuclear localization of the RAI2 protein in the different breast cancer cell lines (Fig. 3D), indicating potential function in transcriptional regulation. Because RAI2 was found to be especially related to both the luminal subtype of ERα-positive breast cancer and to well-differentiated tumors, we analyzed the dynamics of RAI2 protein expression in the course of hormone depletion and pharmacologic treatment with either the ERα antagonist IC118,780 (Fulvestrant) or all-trans retinoic acid (ATRA) in ERα-positive KPL-1 and CAMA-1 cells and ERα-negative MDAMB-231 cells. We found that RAI2 protein expression was downregulated upon hormone depletion and induced in the course of ATRA treatment in KPL-1 and CAMA-1 cells. Also, ERα inhibition led to the induction of RAI2 protein expression in CAMA-1 cells. In contrast, the different treatments had no effect on RAI2 expression in MDA-MB-231 cells (Fig. 3E).

Experimental Modulation of RAI2 Expression in Breast Cancer Cell Lines

The association between RAI2 expression and histologic grade and ERα status led us to investigate whether RAI2 sustains the cellular differentiation of luminal breast cancer cells. Therefore, we first expressed two shRNAs, which efficiently knockdown RAI2 protein expression in MCF-7, KPL-1, and CAMA-1 cells (Fig. 4A). shRNA-mediated knockdown of RAI2 protein expression caused downregulation of ERα protein expression in all three of the tested cell lines and a concomitant downregulation of the expression of GATA3, FOXA1, and GRHL2 proteins, which are known to be key regulators of breast epithelial differentiation (14–16). Furthermore, Western blot analysis further revealed decreased protein expression of the transcriptional coregulators carboxyl-terminal binding proteins (CtBP) 1 and 2 (Fig. 4A) in KPL-1 and CAMA-1 cells and decreased CtBP2 expression in MCF-7 cells.

Furthermore, loss of RAI2 protein expression led to an apparent alteration in cellular morphology. The RAI2-silenced, ERα-positive cell lines MCF-7, KPL-1, and CAMA-1 exhibited enlarged and less refractive cell bodies (Fig. 4B). In addition, some cells demonstrated microfilament branching at cellular edges. Furthermore, a subset of CAMA-1 cells with silenced RAI2 also demonstrated a spindle shape form, which is characteristic of cellular plasticity (Fig. 4B). Although RAI2 knockdown in MCF-7 cells did not affect the number or size of colonies in soft-agar assays, the formed colonies exhibited increased sprouting (Fig. 4C). When grown in 3D Matrigel, colonies formed from RAI2 knockdown in MCF-7 cells did not differ in size or number of cells but demonstrated a cell polarization defect in the form of a notably diffuse distribution of the cis-Golgi matrix protein GM130 (Fig. 4D).

We could detect increased Akt protein phosphorylation at Ser473 as a consequence of RAI2 depletion, which is indicative of activation of the Akt signaling cascade (Fig. 4A). Consequently, we also analyzed whether RAI2 depletion has an influence on cell viability of cultured breast cancer cells that were treated with either MK-2206 or RAD001 that target the Akt or mTOR kinases, respectively. As shown in Fig. 4E, RAI2 depletion caused a significant increase in cell viability in cells that were treated with one particular drug, whereas little combinatory effect was seen in MCF-7 cells and none in KPL-1 and CAMA-1 cells.

Collectively, the data strongly suggest that the RAI2 protein sustains epithelial traits and luminal differentiation in ERα-positive breast cancer cells because RAI2 downregulation induces the loss of essential differentiation-sustaining transcription factors and morphologic changes.

Phenotypic Changes in RAI2-Depleted Breast Cancer Cell Lines

Next, we assessed whether loss of RAI2 protein expression is associated with epithelial-to-mesenchymal plasticity, as strongly suggested by the aberrant cell morphology of RAI2-depleted CAMA-1 cells. We determined the number of mesenchymally transformed CAMA-1 cells by counting cells that stained for F-actin. Approximately 10% of the RAI2-depleted CAMA-1 cells had a spindle-shape characteristic of epithelial-to-mesenchymal transition (EMT; Fig. 5A and Supplementary Fig. S5). Immunofluorescence staining for E-cadherin in MCF-7 and KPL-1 cells (Supplementary Fig. S6) after RAI2 depletion also revealed a decreased E-cadherin expression at cell junctions, which is indicative of a disruption in adhesion junction formation and loss of epithelial properties. However, no spindle-shaped cells were observed in these two cell lines upon RAI2 depletion. We also analyzed alterations in the mRNA expression of selected mesenchymal-specific genes (ZEB1, VIM, SNAI1, and SNAI2) in four RAI2-depleted cell lines by qRT-PCR analysis. Data presented in Fig. 5B indicate significant changes in a variety of mesenchymal markers in the tested cell lines. To obtain further evidence for the potential role of RAI2 in EMT, we examined RAI2 protein expression after EMT induction by TGFB stimulation in MCF-10A cells. In this experimental system, we found downregulation of RAI2 protein expression after TGFB stimulation, which was accompanied by
Figure 4. RAI2 depletion causes dedifferentiation of cultured luminal breast cancer cells. A, Western blot analysis of MCF-7, CAMA-1, and KPL-1 cells expressing either nontarget or RAI2-specific shRNA sequences. Knockdown of RAI2 protein expression was verified 12 days after the initial transduction of the cells. The same cell lysates were subjected to Western blot analysis with the indicated antibodies detecting transcriptional regulators that determine breast epithelial differentiation or the AKT kinase. Equal loading was demonstrated using antibodies recognizing the HSC70 protein. B, analysis of the cellular morphology of RAI2 knockdown cell lines by immunofluorescence staining (blue, DAPI/DNA staining; orange, F-actin). Staining was performed 12 days after the initial transduction of the indicated cell lines. C, anchorage-independently grown MCF-7 breast cancer cell clones in soft agar. Control and RAI2 knockdown cells were cultivated for two weeks in 0.33% soft agar and photographed using a phase-contrast microscope. Representative colonies of each cell clone are shown. D, morphology of MCF-7 breast cancer cell structures in reconstituted basement membrane (Matrigel). Individual control and RAI2 knockdown cells were grown in Matrigel for 2 weeks, fixed, and subjected to immunofluorescence staining with Hoechst DNA stain (blue), phalloidin (red), and α-GM130 (green). E, analysis of cellular viability in shRNA-treated cancer cells determined by the MTT assay. Cells were treated in quadruplicate with the indicated compounds for 72 hours. Error bars, SD of the mean of three independent experiments. P values were calculated with a two-sided Student t test (*, P < 0.05).

We also assessed whether loss of RAI2 protein expression might have an impact on the motility and invasiveness of breast cancer cell lines. As shown in Fig. 5D and E, loss of RAI2 protein expression in the luminal cell lines MCF-7 and CAMA-1 promoted cell migration and invasion. In contrast, when we ectopically expressed HA-tagged RAI2 protein in the highly aggressive basal MDA-MB-231 cell line, we found that forced RAI2 overexpression impaired the migratory and invasive abilities of this cell line (Fig. 5F). Hence, we could show that loss of RAI2 expression contributes to epithelial-to-mesenchymal plasticity and induces a more aggressive phenotype.

Analysis of Molecular Interaction between RAI2 and CtBP Proteins

The RAI2 protein is a largely uncharacterized molecule with unknown molecular function. However, in the course

Analysis was performed as described above except five randomly chosen fields per membrane were counted at ×200 magnification.

of systematically mapping the protein-protein interactions of RAI2, CtBPs were identified as potential interaction partners (17). The CtBP1 and CtBP2 (carboxyl-terminal binding) proteins have been shown to be highly conserved transcriptional corepressors that are important in development and epithelial differentiation (18) and also counteracting several TSGs (19). Proteins reported to bind CtBP usually contain a conserved “PXDLS” CtBP-interaction domain (19). Here, we performed a multiple sequence alignment analysis using Clustal (20) with the primary RAI2 amino acid sequence from different species and found two highly orthologously conserved sequences (ALDLS) in the internal region (amino acids 316–320 and 342–346 in human sequence) of the RAI2 protein (Fig. 6A). Furthermore, the RAI2 protein colocalizes with CtBP1 and CtBP2 in the nuclei of MCF-7 cells stably expressing HA-tagged RAI2 protein as shown by immunofluorescence staining (Fig. 6B). To validate the potential interactions of RAI2 and CtBP2 and analyze the relative importance of the identified potential binding sites, both sites were mutated to 316 ALDAA320 and 342 ALDAA346. In addition, a double mutant was established in which both sites were mutated (termed 4A; Fig. 6C). The subsequent pull-down experiments (Fig. 6D) demonstrated that when any of the sites were mutated, there was a marked decrease in coprecipitated CtBP2, with the first CtBP binding site being slightly less important for CtBP2 binding, which mirrors the results from subsequent fluorescence anisotropy analysis. When both sites were mutated, no CtBP2 binding could be detected. To further characterize the interaction between CtBP2 and RAI2, we used fluorescence anisotropy to quantify the binding of CtBP2 and two fluorescent peptides representing fragments 313–326 and 339–350 of RAI2, which comprise binding motifs 1 and 2, respectively. For both peptides, the experiments demonstrated specific binding with a dissociation constant in the low micromolar range (Fig. 6E).

RAI2 Is Downregulated in Early Metastasized Breast Tumors

**DISCUSSION**

In this study, we identified a set of transcripts associated with the early hemogenous spread of tumor cells to the bone marrow as one of the major sites of metastases in breast cancer. Among those DTC-associated genes, RAII was the only gene associated with OS in all of the tested cancer datasets, suggesting an explanation for the correlation between the diminished RAII expression and lymph node metastasis. RAII has been hypothesized to function in protein binding (23), the RAII protein sequence does not share any known protein domains with other proteins. Thus, RAII represents a unique protein. Thus far, RAII expression has been associated with neural differentiation (12), and RAII transcripts have been detected in different human adult and fetal tissues (23).

Our expression analysis of breast tumors and breast cancer cell lines showed that RAII transcript and protein expression was significantly increased in ERα-positive, luminal breast tumors and cell lines compared with basal or HER2 overexpressing tumors. Furthermore, we showed that increased RAII expression was also associated with well-differentiated breast tumors and correlated with the expression of good prognostic factors such as low tumor grade. These results suggest that RAII loss is a common characteristic of primary and cultured tumor cells that have acquired an aggressive phenotype, strengthening the hypothesis that RAII downregulation might be functionally important. RAII silencing led to reduced expression of the ERα receptor in luminal breast cancer cell lines. Although the exact meaning and molecular mechanism behind this observation remains to be elucidated, Gattelli and colleagues (24, 25) have reported that integration of viral mouse mammary tumor virus (MMTV) into the RAII locus is associated with the emergence of recurrent and hormone-independent breast tumors, emphasizing a particular role for RAII depletion in the progression from hormone-dependent to hormone-independent breast tumors. Concordantly, we found that RAII protein expression is downregulated upon hormone depletion and upregulated in the course of pharmacologic reduction of ERα, further indicating that RAII might be an active part in the transcriptional network of hormonal responses in breast cancer.

Silencing RAII in luminal breast cancer cell lines induced morphologic changes together with the induction of mesenchymal marker expression and a more aggressive phenotype characterized by increased cell migration and invasiveness, indicating that loss of RAII function induces epithelial-to-mesenchymal plasticity. In addition to the observed reduction in ERα protein expression, we found markedly reduced protein expression of the GATA3, FOXA1, and GRHL2 transcription factors, which are pivotal for determining the epithelial differentiation of breast cancer cells (14–16, 26–28). Importantly, mere loss of the transcription factor GATA3 has been shown to actively drive dedifferentiation and marks the onset of tumor dissemination and metastasis formation in different breast cancer models (29, 30). Because of the well-established association between metastatic progression and loss of differentiation (6–8, 16), this appears to be a plausible explanation for the correlation between the diminished RAII expression in early-stage primary tumors and the presence of DTCs in the bone marrow. Also, treatment with ATRA, a regulator of differentiation, in both normal and tumor cells led to the induction of RAII. Our findings thus provide evidence that RAII is a bona fide determinant of differentiation in breast cancer; therefore, loss of RAII expression might represent a key event for early steps of the metastatic cascade by promoting dedifferentiation, cellular plasticity, and thus tumor cell dissemination. On the other hand, tyrosine kinase receptor-A and the integrin-2 pathways were the most significantly deregulated pathways in nonluminal MDA-MB-231
cells overexpressing RAI2, suggesting that in this cell line cellular adhesion and/or signal integration and not mesenchymal-to-epithelial transition might be important for the observed phenotypic changes. We therefore conclude that it is most likely that the RAI2 protein exhibits cell type–specific functions beyond the regulation of differentiation.

Our primary sequence analysis of the RAI2 amino acid sequence revealed a nonconsensus bipartite CtBP-interaction domain, which was shown to mediate RAI2 binding to the CtBP transcriptional repressor protein. Such nonconsensus bipartite CtBP-interaction domains are also found in some other, mostly viral, proteins, creating efficient binding to CtBP proteins (31). Binding of the adenoviral E1A protein to CtBP via PXDLS motifs has been reported to negatively modulate transformation, tumorigenicity, and metastasis in cell line models (32). Here, we have provided evidence that the inhibitory effects of the RAI2 protein on cellular motility are dependent on interaction between RAI2 and CtBP proteins and most of the RAI2-induced gene expression changes that occurred in MDA-MB-231 cells were not seen in cells overexpressing the CtBP binding-deficient RAI2 protein. CtBP1 and CtBP2 are closely related, evolutionarily conserved transcriptional corepressors functionally linked to tumorigenesis and tumor progression by promoting EMT and mediating the repression of several TSGs (19). It was recently shown that among the diverse direct transcriptional targets of CtBP in breast cancer cell lines are the epithelial-specific transcription factors GATA3, FOXA1, and GRHL2 (18). Moreover, CtBP proteins control epithelial-specific gene expression in different cell types (33, 34), indicating that these factors are acting as ubiquitous regulators of epithelial differentiation. Because we found a significant correlation of high RAI2 gene expression with prolonged survival not only in breast cancer but also in lung, colon, and ovarian cancers, the molecular interaction of RAI2 protein and CtBP factors might be important for maintaining epithelial traits in general. Clearly as a putative transcriptional regulator, RAI2 is envisaged to be able to regulate different cellular processes, some of which might partially be cell type–specific, in a similar way as the interaction partner CtBP.

Another interesting finding is that loss of CtBP protein expression is observed in both RAI2-silenced luminal breast cancer cells and in MDA-MD-231 cells overexpressing CtBP binding-deficient RAI2 protein. These results imply that RAI2 is directly involved in the regulation of CtBP expression. On the basis of the nuclear colocalization of RAI2 and CtBP, direct interaction with CtBP, and the overlap in regulated genes, we hypothesize that RAI2 might function as a transcriptional coregulator that sustains differentiation of breast epithelial cells by controlling the expression of several key regulators of breast epithelial integrity.

We also discovered in RAI2-depleted cells increased phosphorylation of AKT proteins at S473 and significant increase in cell viability in cells treated with MK-2206 or RAD001 (everolimus) that both target the AKT–mTOR pathway. Because RAD001 has already been approved in combination with exemestane for treating postmenopausal hormone-receptor–positive advanced breast cancer (35) and a clinical phase II trial of MK-2206 in treating patients with advanced breast cancer is ongoing (36), RAI2 might represent a predictive marker for response to AKT–mTOR targeted therapeutic strategies. Accordingly, RAI2 expression might be used in the future for optimizing patient selection and clinical benefit, respectively. Further studies are needed to analyze this clinical implication. Furthermore, different studies have identified the AKT pathway as a major source of survival signals for enabling latent DTCs and circulating tumor cells (CTC) to survive in the circulation and secondaries (1, 37, 38). Interestingly, mAKT and AKT3-positive DTCs were detected in bone marrow samples from patients with lung cancer, and AKT1/AKT3 regulated the proliferation and survival of these DTCs (39). It has been shown that the CtBP proteins, in addition to controlling epithelial gene expression, also modulate the cellular threshold for apoptotic responses (33, 34). These data lead to the hypothesis that RAI2 depletion is not only involved in the onset of dissemination but might also affect survival of DTCs in the bone marrow. Importantly, bone marrow represents a retinoic acid–rich microenvironment (40); also, retinoic acid signaling regulates differentiation and self-renewal of hematopoietic stem cells in the bone marrow (40, 41). Because DTCs may lodge in the hematopoietic stem cell niches in bone marrow (42), DTCs might be exposed to the same regulatory mechanisms and therefore the RAI2 protein might also be involved in the control of overt bone metastasis formation.

In summary, the results described here indicate that loss of RAI2 expression might represent a so far undiscovered key event at the onset of metastatic progression. Because of a swift recovery of RAI2 expression in the knockdown cell lines used here, their usage is thus restricted to in vitro applications. Further studies, including molecular analysis of DTCs and CTCs, are certainly needed to dissect the exact role of RAI2 in individual steps of the metastasis formation. Understanding the biology of metastasis-suppressing proteins, such as RAI2, provides valuable mechanistic insights that may be translated to novel therapeutic strategies (10). Future studies will show whether the RAI2 protein is suitable to act as a druggable target or whether RAI2 expression might be used as a novel predictive marker.

**METHODS**

**Study Design**

To identify novel genetic lesions especially related to the onset of metastasis formation, we compared in this retrospective study whole-genome expression profiles of early metastasized primary breast tumors with nonmetastasized tumors using the presence of DTCs in the bone marrow as an indicator for early occurring metastasis. For gene-expression profiling, primary tumor samples were collected from 32 primary lymph node–negative, hormone receptor–positive untreated breast cancer patients. Patients underwent surgical resection at the University Medical Center, Hamburg-Eppendorf (UK; Hamburg, Germany). Tumor samples were divided into two groups based on patient DTC status: (i) DTC-negative (n = 16) and (ii) DTC-positive (n = 16) samples, which were classified as cMO(i = 16) and tumoral node–metastasis (TNM) staging (43). The cases were matched for age, histology, and TNM status. The patient clinical data are summarized in Supplementary Table S1. For quantitative RT-PCR analysis, an additional set of 76 early-stage primary breast tumor samples from UK and University Hospital Tübingen (Tübingen, Germany) were analyzed, including 36 DTC-positive and 40 DTC-negative cases (Supplementary Table S1). Fifteen of these patients overlapped with those used in the initial array experiments. This study received ethics review board approval, and sample donors gave informed written consent.
Bone Marrow Analysis

The procedures used for the isolation and immunocytochemical detection of tumor cells in the bone marrow have been described in detail (44). Bone marrow was aspirated from the upper iliac crest, and mononuclear cells isolated by density centrifugation were cyt-centrifuged onto glass slides (2×10^6 cells/patient). DTCs were detected by immunocytochemical staining using the monoclonal antibody A45-B/B3 (Micromet). An isotype-matched, murine monoclonal antibody (MOPC 21, IgG1; Sigma-Aldrich) served as a negative control. Screening for CK-positive cells was performed in an automated fashion (ACIS system) using color-based imaging technology and microscopy to automatically scan and analyze immunohistochemically stained slides (45).

Gene Expression Profiling and In Silico Validation

The detailed procedure is provided in the Supplementary Methods. Microarray data of patients are available at ArrayExpress accession no. E-MTAB-5015. Microarray data and at Gene Expression Omnibus (GEO) for the cell line experiments, according to MIAME standards. Microarray data of MDA-MD-231 cells overexpressing RAII2 and CtBP binding-deficient mutant are available by GEO accession no. GSE 65489.

Quantitative Real-Time RT-PCR Analysis

qRT-PCR analysis of the patient samples was performed with 150 ng of total RNA isolated by the RNeasy Micro Kit as described above. The RNA was reverse transcribed using the First Strand cDNA Synthesis Kit (Thermo Scientific), and the mRNA quantity was estimated by fluorescence qPCR based on SYBR Green and random hexamers using the following primer sequences: RAI2-F: CGGTCATTAAGATGGGAAG and RAI2-R: GAGGCTCGGATTTCCGGTG. The qRT-PCR reactions were run in triplicate and performed using the MyCycler Eppendorf Realpelt thermal cycler. Data were analyzed by applying the ΔΔCt method using RPLPO expression for normalization. The results, expressed as fold changes, were set in relation to Universal Human Reference (UHR) expression. For cell line analyses, 1 μg of total RNA was extracted using the NucleoSpin RNA Kit (Machery Nagel) according to the standard protocol. RNA was transcribed using the First Strand cDNA Synthesis Kit (Thermo Scientific) and random hexamers. qRT-PCR analyses with specific primers (Supplementary Table S5) were performed as described above, but fold changes were set in relation to the parental cell lines.

Cell Culture

MDA-MD-231 and SK-BR-3 cells were obtained from the ATCC. BT-549, BT-474, T-47D, and MDA-MD-468 cells were obtained from Cell Lines Service. MCF-7 and Phoenix amphotrophic retroviral packaging cells were a kind gift from Dr. Volker Assmann (UKE). CAMA-1 and KPL-1 cells were a kind gift from Dr. K. Iljin (VTT, Espoo, Finland) and MCF-10A cells were a kind gift from Dr. Steven Almo. Authentication of cell lines used in functional assays was conducted with short tandem repeat (STR) profiling to exclude cross-contamination between the cell lines. Authentication was last confirmed on February 12, 2014. Cells were grown as monolayers according to standard conditions in either DMEM or RPMI supplemented with 10% fetal calf serum (FCS; PAAL) and 2 mM L-glutamine at 37°C in a humidified atmosphere containing 10% CO2 or 5% CO2, respectively. MCF-10A cells were cultured in (1:1) DMEM/F12 medium supplemented with 5% horse serum, 100 ng/mL cholera toxin, 20 ng/mL EGF, 500 ng/mL hydrocortisone, and 10 μg/mL insulin. For induction of EMT, cells were stimulated with 10 ng/mL TGFβ1 (R&D Systems) for 48 hours. For hormonal depletion, cells were cultured in medium containing charcoal-stripped instead of normal FCS for 5 days. Treatment with either 1 μmol/L ATRA or 100 nmol/L JC1182,780 was done by adding drugs to standard medium for 5 days. Analysis of cellular viability was done by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay. Five thousand cells of the analyzed cell line were plated in quadruplicate and treated with either MK-2206 or RAD001 for 72 hours. Relative viability was calculated by determining absorbance at 570 nm and normalization to carrier treated cells.

3D Culture

The detailed procedure was previously described (46) and is provided in the Supplementary Methods.

RAII2 Plasmid Construction and Viral Transduction

The RAI2 coding sequence was RT-PCR amplified from Hs578t cells with the oligonucleotides 5′-CAAGTGCCATCAGAGCTGAG-3′ and 5′-CTTTCTTGGAAAAAGGTGGCCAGC-3′ using Pfu DNA polymerase (Agilent Technologies), and it was inserted into the pcMV3 expression plasmid (Genelantis) using EcoRI and KpnI restrictions sites. To generate an RAII2 protein incapable of CtBP binding, site-directed mutagenesis was performed with the oligonucleotides 5′-CAGGAGCGCTTGGATGCGCGCTATGACAGTGC-3′ and 5′-GACCTGCTTGGATGCGCGCTATGACAGTGC-3′ and/or 5′-GCAGCCCTGACGCGCGCTGACAGTGC-3′ and 5′-GGTTGGGCCAGCTGCTGACAGTGC-3′. The PCR products were digested with DpnI (New England Biolabs) and transformed into chemically competent bacteria. Positive clones were verified for the correct sequence by Sanger sequencing. To generate a retroviral expression vector, the HA-tagged RAII2 cDNA sequence was reamplified with Pfu DNA polymerase and cloned into the pMXs-IREs-Puro packaging plasmid (Cellbios) using EcoRI and NotI restriction sites. To produce retroviral particles, 6NX-ampho packaging cells were transfected with 4 μg of retroviral expression plasmid using Lipofectamine 2000 (Life Technology). For transduction, 500 μL of viral supernatant was added to 50% confluent recipient cultures in 6-well plates containing 1 mL DMEM + 10% FCS. Positive selection was begun 24 hours after transduction using 2 μg/mL of puromycin containing medium. Cells were subsequently maintained under puromycin selection for 4 days.

shRNA-Mediated Knockdown of Gene Expression

Lentiviral pLKO.1 shRNA vectors were targeted against human RAII2 (shRNA1 TRCN0000139927 and shRNA2 TRCN0000441623) were obtained from the RNAi Consortium. A pLKO.1 vector harboring a scrambled nontargeting shRNA sequence served as a negative control. Lentiviral supernatants were generated by transfecting HEK 293T cells with these plasmids by using a three-plasmid packaging system according to standard protocols. Supernatants were harvested, sterilized, and filter-sterilized. Afterward,cells were transduced with a virus-containing supernatant. Transduced cells were selected by puromycin. Because of the recovery of RAII2 expression, all experiments were performed within 8 to 14 days after the initial transduction.

Immunoprecipitation

HEK 293T cells were transduced with 4 μg of pcMV3 expression plasmids containing either the wild-type or mutated RAII2 cDNA sequence using Lipofectamine 2000 (Life Technology). After 48 hours, the cells were lysed in buffer containing 50 mMol/L Tris-HCl, pH 8, 0.4% NP-40, 300 mMol/L NaCl, and 10 mMol/L MgCl2 plus phosphatase and protease inhibitors. Afterward, nuclei were collected by centrifugation, and equal amounts of dilution buffer containing 50 mMol/L Tris-HCl, pH 8 and 0.4% NP-40 was added to each sample. Precipitation of the protein complexes was performed for 3 hours at 4°C with 1 mg of total protein from each sample and 40 μL of anti-HA agarose slurry (clone 1233; Abcam). Precipitation and washing was performed in buffer containing 50 mMol/L

For invasion assays, BD BioCoat Matrigel Invasion Chambers (BD) were used. Filters were run in duplicate, and results are expressed as the state of detection and characterization. Pathobiology 2008; 75: 140–8.

Disclosure of Potential Conflicts of Interest

No potential conflicts of interest were disclosed.

Authors’ Contributions

Conception and design: S. Werner, V. Poggenberg, A. Trumpp, S.A. Johnsen, M. Wilmanns, K. Pantel, H.Wikman

Development of methodology: S. Werner, B. Brors, J. Eick, E. Marques, J. Klefström, H. Wikman

Acquisition of data (provided animals, acquired and managed patients, provided facilities, etc.): S. Werner, J. Eick, E. Marques, V. Poggenberg, A. Parret, S. Riethdorf, U. Bedi, I. Baccelli, T. Fehm, J. Klefström, H. Wikman

Writing, review, and/or revision of the manuscript: S. Werner, B. Brors, E. Marques, D. Kemming, A.W. Wood, H. Neubauer, S. Riethdorf, M. Jücker, T. Fehm, A. Trumpp, J. Klefström, V. Müllcr, K. Pantel, H. Wikman

Administrative, technical, or material support (i.e., reporting or organizing data, constructing databases): S. Werner, M. Jücker, M. Wilmanns, V. Müllcr, K. Pantel, H. Wikman

Study supervision: S. Werner, S.A. Johnsen, K. Pantel, H. Wikman

Other (generation of reagents used in study): A.W. Wood

Acknowledgments

The authors are grateful for the skilful technical assistance of Kathrin Eyllmann and Jolanthe Kropidowski. The authors thank Drs. Volker Assmann and Sabrina Frey for providing technical advice and reagents. They also thank the microarray unit of the DKFZ Genomics and Proteomics Core Facility for providing excellent service in array-based transcriptomics.

Data and materials availability: Patient expression data were loaded into ArrayExpress. Experiment name: Comparison of expression profiles of breast tumors with or without presence of DTCs. ArrayExpress accession: E-MTAB-2501. All plasmids and cell lines are available upon request. Cell line expression data is available at GEO (GSE65489).

Grant Support

This project was funded by the EU (DISMAL, DISSECT, ERC advanced Investigator Grant, to K. Pantel, PI) and DFG RA12 5/2012-4/2015 grants. B. Brors and R. Eils received funding through DISMAL, and from the German Federal Ministry of Research and Education through grant no. 0316168C.
