Abstract

Through unbiased metabolomics, we identified elevations of the metabolite 2-hydroxyglutarate (2HG) in renal cell carcinoma (RCC). 2HG can inhibit 2-oxoglutarate (2-OG) dependent dioxygenases which mediate epigenetic events including DNA and histone demethylation. 2HG accumulation, specifically the D-enantiomer, can result from gain of function mutations of isocitrate dehydrogenase (IDH1, IDH2) found in several different tumors. In contrast, kidney tumors demonstrate elevations of the L-enantiomer of 2HG (L-2HG). High 2HG tumors demonstrate reduced DNA levels of 5-hydroxymethylcytosine (5hmC) consistent with 2-HG mediated inhibition of TET (Ten Eleven Translocation) enzymes which convert 5-methylcytosine (5mC) to 5hmC. L-2HG elevation is mediated in part by reduced expression of L-2HG dehydrogenase (L2HGDH). L2HGDH reconstitution in RCC cells lowers L-2HG and promotes 5hmC accumulation. Additionally, L2HGDH expression in RCC cells reduces histone methylation and suppresses in vitro tumor phenotypes. Our report identifies L-2HG as an epigenetic modifier and putative oncometabolite in kidney cancer.

Significance.

Here, we report elevations of the putative oncometabolite L-2HG in the most common subtype of kidney cancer and describe a novel mechanism for the regulation of DNA
5hmC levels. Our findings provide new insight into the metabolic basis for the epigenetic landscape of renal cancer.

Introduction

One of the clearest examples of the role of metabolism in cancer is the recent identification of oncometabolites, small molecules with putative oncogenic properties. Mutations in tumors of fumarate hydratase (FH), succinate dehydrogenase (SDH), and isocitrate dehydrogenase 1 and 2 (IDH1/2) lead to elevated levels of fumarate, succinate, and 2-hydroxyglutarate (2HG), respectively(1, 2). In FH and SDH mutations, precursor metabolites (fumarate and succinate) accumulate due to loss of enzymatic activity. In the case of IDH1 and IDH2, highly conserved mutation “hot spots” in DNA of tumors result in the formation of a “neoenzyme” that leads to elevated 2HG (specifically the D- enantiomer) in gliomas and acute myeloid leukemias (AMLs) as well as other malignancies(2, 3). A unifying theme linking these three oncometabolites is their ability to inhibit a class of enzymes referred to as 2-oxoglutarate (2-OG) dependent dioxygenases (2OGDs). Members of this enzyme family include prolyl hydroxylases (PHDs), which are involved in the regulation of the transcription factor Hypoxia Inducible Factor-1α (HIF-1α), histone demethylases, and DNA hydroxylases(4). In the case of succinate accumulation, feedback inhibition is a proposed mechanism as succinate is a product of 2-OGD catalyzed reactions. In the case of fumarate and 2HG, competitive inhibition is the proposed mechanism due to structural similarity with the cofactor 2-OG. Collectively, these data suggest that metabolic perturbations in cancer can inhibit 2-OGD activities with potential effects on tumorigenesis.

Recent studies have focused on the ability of oncometabolites to inhibit DNA hydroxylation by the TET (Ten Eleven Translocation) enzymes (TETs 1-3) which convert 5-methylcysteine (5mc) to 5-hydroxymethylcytosine (5hmC). The oxidation of 5mc to 5hmC has
been proposed to promote the demethylation of DNA, either via active or passive means(5). Alternatively, 5hmC has been proposed to be its own epigenetic mark with distinct effects on DNA architecture and gene expression(6). Despite these conflicting views, emerging data demonstrates reduced 5hmC levels in human cancer as well as animal tumor models indicating a role for 5hmC loss in carcinogenesis(7, 8). Further evidence for the role of 5hmC loss in malignancy is provided by the fact that TET2 is commonly mutated in human myeloid malignancies including acute myeloid leukemia (AML) as well as other myeloid disorders(9, 10). 2HG can inhibit TET enzymatic activity and promote loss of 5hmC(11). These studies have primarily examined the role of the D enantiomer of 2HG (D-2HG) which is markedly elevated in the setting of IDH mutations. Notably, both cell-free and in vitro studies demonstrate that the L enantiomer (L-2HG) is more potent at inhibiting 2OGDs including the TET enzymes(11, 12).

In this report, we demonstrate elevations of 2HG in clear cell renal cell carcinoma (ccRCC), the most common histological subtype of kidney cancer. In contrast to IDH mutant tumors, ccRCCs demonstrate elevations of L-2HG. In concordance with the ability of 2HG to inhibit TET enzymatic activity, tumors with elevations of 2HG demonstrated reduced levels of 5hmC in genomic DNA. We provide evidence that reduced mRNA and protein expression of L-2HG dehydrogenase (L2HGDH) in ccRCC promotes 2HG accumulation and 5hmC loss. Bioinformatic analysis demonstrates that copy number loss is associated with reduced L2HGDH expression in ccRCC. L2HGDH reconstitution in RCC cells lowers L-2HG, promotes 5hmC accumulation, and suppresses in vitro tumor phenotypes. Collectively, our data demonstrate a putative oncometabolite elevated in ccRCC with effects on the kidney cancer epigenome.

Results

We analyzed 59 matched tumor/normal pairs utilizing an unbiased metabolomics profile (manuscript in preparation). This initial analysis identified statistically significant elevations of 2HG (greater than 5-fold) in ccRCC relative to normal renal parenchyma (Figure 1A). However,
multiple tumors demonstrated elevations of 2HG more than 10-fold higher in normal tissue. Investigation for somatic mutations in RCC using both the cBioPortal for Cancer Genomics (to analyze TCGA data sets) and the Sanger COSMIC database did not demonstrate any evidence for IDH mutations in ccRCC (data not shown). 2HG is known to occur in two enantiomers, D(R) and L(S). We therefore analyzed metabolite extracts from both high and low 2HG tumors via liquid chromatography tandem mass spectrometry (LC-MS/MS) for levels of each 2HG enantiomer (Figure 1B). Of notable significance is that the predominant enantiomer present in these cells is the L enantiomer (Figure 1B). Analysis of high 2HG tumors demonstrated that the L enantiomer accounted for approximately 90% of the 2HG present in these tumors (Figure 1C). We validated our findings in a separate cohort (Figure 1D). Clinical information present on this cohort is provided in Supplemental Table 1. We therefore analyzed a panel of RCC lines for 2HG elevations in addition to non-transformed renal epithelial cells HK-2 and HRE 152. Consistent with our tissue analysis, several RCC lines demonstrated increases in 2HG with predominant contribution made by the L- enantiomer (Figure 1E). Notably, L-2HG elevation was found in cells both with and without alterations of VHL, the most commonly altered gene in ccRCC. Analysis of tumor samples confirmed L-2HG elevation in tumors both with and without VHL coding mutations (supplemental Table 2). Collectively, these demonstrate elevations of L-2HG in ccRCC.

2HG elevations have been identified as inhibiting TET enzymatic activity thereby leading to reduced levels of 5hmC in the context of IDH mutation(11). We utilized an ELISA-based assay to quantitate absolute 5hmC levels. To validate the assay, we overexpressed the catalytic domains (CD) of TET1 and TET2 in HEK-293 cells in addition to enzymatically inactive mutants (CM) of TET1 and TET2. Consistent with previous data(11), cultured cells including HEK-293 cells express low levels of 5hmC (Figure 2A). However, transient expression of TET1 or TET2 CD was able to raise 5hmC levels, whereas CM forms of either TET1 or TET2 could not (Figure 2A). We therefore examined levels of 5hmC in the context of 2HG elevation. Consistent with
prior data, L-2HG octyl-ester treatment reduced DNA 5hmC levels in HK-2 renal epithelial cells (Figure 2B). We confirmed increases in intracellular 2-HG levels following ester treatment (data not shown). Tumors with elevated 2HG levels demonstrate significantly reduced levels of 5hmC relative to matched normal tissue on ELISA analysis (Figure 2C-upper panel). Dot-blot assay with an antibody specific to 5hmC in DNA identified that high 2HG tumors demonstrated reduced levels of 5hmC relative to normal kidney (Figure 2C-lower panel). In contrast, tumors with low 2HG levels did not demonstrate reduced 5hmC levels (Figure 2D). Collectively, these data indicate that raised levels of 2HG in ccRCC are associated with 5hmC loss.

We next wanted to identify potential factors that promote L-2HG accumulation in ccRCC. L-2-hydroxyglutaric aciduria is an inborn error of metabolism linked to loss of function mutations of the gene encoding L-2HG dehydrogenase (L2HGDH) (13). Notably, several RCC lines demonstrated reduced mRNA and protein expression of L2HGDH relative to nontransformed renal epithelial cells (Figures 3A and 3B). We found that A498 and RXF-393 demonstrate elevated L-2HG levels with concomitant reduced L2HGDH mRNA/protein expression (Figures 1E, 3A, 3B). These data prompted us to examine the relationship between L-2HG levels and L2HGDH expression in patient samples. We analyzed L2HGDH mRNA expression in normal kidney, low L-2HG tumors, and high L-2HG tumors. Elevated L-2HG tumors had higher ΔCt L2HGDH (Ct L2HGDH- Ct RPL0) indicating lower L2HGDH expression when compared with low L-2HG tumors and normal kidney (Figures 3C and 3D). Immunoblot analysis confirmed mRNA findings as primary tumors with elevated 2HG had reduced protein levels of L2HGDH relative to normal tissue (Figure 3E). Immunohistochemical analysis also demonstrated reduced L2HGDH expression in high L-2HG tumor relative to normal kidney. Notably, proximal tubule cells, the likely cell of origin for ccRCCs, have prominent L2HGDH expression relative to distal tubule cells (Figure 3F). We next examined if re-expression of L2HGDH in RCC cells could lower L-2HG levels. Using lentivirus, we stably expressed L2HGDH cDNA in RCC cells and confirmed expression by immunoblotting (Supplemental Figure 1S). L2HGDH expression
significantly reduced intracellular L-2HG levels in A498 (figure 3G). The *L2HGDH* locus is located on chromosome 14q, a region commonly lost in ccRCC(14). We therefore examined the relationship between copy number loss and gene expression alterations with Level 3 RNAseq data from TCGA. ccRCC tumors with loss of a single copy (i.e. loss of heterozygosity) were associated with significantly reduced mRNA expression of L2HGDH compared with diploid tumors (Figure 3H). Collectively these data demonstrate that reduced expression of L2HGDH promotes L-2HG accumulation in ccRCC.

We next determined whether modulation of L2HGDH expression could impact levels of 2HG as well as 5hmC levels. We therefore cotransfected HEK-293 cells with TET1 CD (to raise 5hmC levels to a detectable range) and either siRNA to L2HGDH or control siRNA. Immunoblotting confirmed TET1 CD expression and knockdown of L2HGDH (Supplemental Figure 2S). Consistent with its role in L2HG metabolism, L2HGDH knockdown led to raised levels of cellular 2HG (figure 4A – left panel). Concomitantly, we identified decreased levels of 5hmC with L2HGDH knockdown consistent with the ability of L2HG to inhibit TET enzymatic activity (Figure 4A- right panel). Similar results were obtained in HK-2 renal epithelial cells (figure 4B- and Supplemental Figure 2S). As a complement to our knockdown approach, we overexpressed TET1 CD and either control vector or L2HGDH cDNA in HEK-293 cells. Immunoblotting confirmed transgene expression (Supplemental Figure 3S). Under basal culture conditions, L2HGDH overexpression had little impact on cellular 2HG levels consistent with the fact that HEK-293 cells express high levels of L2HGDH mRNA and protein levels (data not shown). We therefore challenged cells with esterified L-2HG (octyl-2HG) to raise intracellular levels of 2HG. Following octyl-2HG challenge, L2HGDH cDNA overexpression in HEK-293 cells led to reduced cellular 2HG levels relative to control cells consistent with the role of L2HGDH in the metabolism of L-2HG (figure 4C-left panel). Consistent with reduced 2HG levels, L2HGDH overexpressing cells demonstrate increased 5hmC levels compared to vector control transfected cells (figure 4C-right panel). Consistent with these data, reexpression of
L2HGDH in A498 cells led to an increase in 5hmC levels as compared with control vector (figure 4D). As noted, prior studies have demonstrated that L-2HG can inhibit histone demethylases and hence promote histone methylation. We therefore examined the impact of L2HGDH effects on histone methylation patterns. Stable expression of L2HGDH in both A498 and RXF393 cells led to reduced H3K27me3 and H3K9me3 levels consistent with reduced L-2HG levels and ensuing activation of histone demethylase activity (Figure 4E). Collectively, these demonstrate that modulation of L2HGDH expression can impart effects on both DNA and histone modifications. Given the emerging role of epigenetic alterations in RCC, we examined the effects on L2HGDH expression on in vitro phenotypes. Notably, L2HGDH expression reduced proliferation and colony formation in A498 and RXF393 RCC cells (Figure 4F and 4G).

Discussion

Here, we demonstrate elevations of L-2HG in clear cell renal cell carcinoma, the most common histology. We also demonstrate a novel mechanism for L-2HG elevations via the reduced mRNA and protein expression of L2HGDH in part due to loss of the L2HGDH gene. Previous studies demonstrate that elevated cellular levels of L-2HG are present in an inborn error of metabolism that results from L-2HG dehydrogenase (L2HGDH) deficiency(13). Although rare, a significant proportion of patients develop tumors suggesting a role for L-2HG in carcinogenesis. In particular, L2HGDH deficiency has been linked to brain tumors and Wilm’s tumor(15, 16). To the best of our knowledge, this is the first report to demonstrate elevations primarily of the L- enantiomer in cancer. This is in contrast to elevations of D-2HG that have been identified in a growing list of cancers with IDH mutations. Notably, a recent study reported 2HG increases in breast cancers in the absence of IDH mutations(17). However, the specific enantiomer was not reported.

Our data do not exclude alternative mechanisms for L-2HG accumulation in ccRCC. Prior studies have demonstrated that “off-target” activity of malate dehydrogenase
(MDH1/MDH2) can convert 2-OG to L-2HG(18). Substrates for this reaction include glucose and glutamic acid(19). It is well established that glutamine can be converted to glutamate (via glutaminases), which can be eventually converted to 2-OG. This is particularly relevant given recent studies by Wise et al. demonstrating that HIF can promote modest increases in 2HG synthesis via IDH mediated reductive carboxylation of glutamine-derived 2-OG(20). However, enantiomeric resolution of 2-HG was not performed in this study. Nevertheless, given recent studies on reductive glutamine metabolism in VHL deficient RCC cells (which demonstrate HIF stabilization)(21, 22), these alternative mechanisms warrant further investigation.

2HG is part of a growing list of small molecules referred to as oncometabolites, which refers to small molecules with putative transforming properties. Recent studies have linked D-2HG to the promotion of leukemogenesis(23). In particular, D-2HG promotes cytokine independence and blocks differentiation in hematopoietic cells. Mutations in tumors of fumarate hydratase (FH) and succinate dehydrogenase (SDH) lead to elevated levels of fumarate and succinate, respectively, due to loss of enzymatic activity. Germline mutations of FH predispose individuals to the development of renal cancer as well as cutaneous and uterine leiomyomas(24). Germline SDHB mutations have also been linked to renal cancer as well pheochromocytomas and paragangliomas(25, 26). Hence, a notable finding is that all 3 metabolites are linked to RCC.

A unifying theme amongst these three oncometabolites is their ability to inhibit 2-oxoglutarate (2-OG) dependent dioxygenases (2OGDs). Members include prolyl hydroxylases (PHDs), 5mC DNA hydroxylases (TETs 1-3), and histone demethylases. Multiple studies have demonstrated that fumarate, succinate, and 2HG can inhibit TET enzymatic activity(11, 27, 28). Consistent with these data, we identified reduced 5hmC levels in tumors with elevations of 2HG. The fold changes of 2HG we have identified in RCC are more modest relative to the 2HG elevations noted in the context of IDH mutations. A prior study by Choi et al. analyzed 2-HG (both D and L) in IDH mutant tumors by the same methodology as our study(29). The reported
range of D-2HG in these tumors ranged from ≈20-200 nmol/mg protein. We identified multiple tumors with L-2HG levels within 10-fold of *IDH* mutant tumors. Notably, prior studies have demonstrated that the L enantiomer of 2HG is a far more potent inhibitor of 2OGDs (including TETs) compared to the D enantiomer(11, 12, 27).

Given the multiple 2OGDs, it may be difficult to discern which of these are significant from a tumorigenic standpoint. Several lines of evidence suggest the importance of 2-OGDs relating to histone and DNA biology in kidney cancer. Recurrent mutations of *UTX* which encodes a H3K27 demethylase that requires 2-OG have been found in RCC(30). In addition, recent studies demonstrate increased expression of the catalytic subunit of the polycomb repressive complex 2 (PRC2), enhancer of zeste homologue 2 (EZH2), in ccRCC(31, 32). The PRC2 promotes H3K27 methylation. Our findings demonstrate that reexpression of L2HGDH in RCC cells reduces H3K27 methylation. Collectively, these data strongly suggest the importance of this histone mark in renal carcinogenesis. A notable finding from two independent studies in AML is that *TET2* mutations are mutually exclusive from *IDH* mutations(10, 33). The common link between these two seemingly unrelated mutations is their effect on TET enzymatic activity- either through loss of function mutations (*TET2* mutations) or, in the case of *IDH* mutation, 2HG mediated inhibition of TET enzymatic activity through competition with the cofactor 2-OG. As noted, mutations of *TET2* have been identified in myeloid disorders such as AML and glioma. Notably, recent deep sequencing efforts on RCC has identified *TET2* mutations in RCC(34). However, whether these mutants result in loss of function with effects of 5hmC levels has not been determined. Additionally, reduced expression of TET enzymes has been demonstrated in a variety of tumors(7, 8). Correspondingly, reduced levels of 5hmC have been identified in cancer as well(7, 8). Given these data, L-2HG like has multiple biologically relevant 2-OGD targets.

As noted previously, the TETs promote the conversion of 5mC to 5hmC which is currently thought to promote DNA demethylation. Hence, it might be expected that loss of TET
activity, either due to mutation or inhibition, would result in DNA hypermethylation. However, the reported effects on global DNA methylation in the context of TET2 mutations in myeloid disorders has been conflicting(10, 35). Alternatively, 5hmC may represent its own epigenetic mark with specific effects on gene expression, perhaps through the recruitment of specific transcriptional regulators. These data point to the complexity of 5hmC biology and the need for further studies clarifying the mechanisms by which this DNA modification impacts gene methylation, regulation and expression in the setting of elevated L-2HG.

In summary, our data demonstrate elevated levels of 2HG in RCC, specifically the L-enantiomer. We demonstrate that elevations of 2HG are associated with loss of 5hmC levels in RCC samples and that these changes are mediated by the reduced expression of L2HGDH. Specifically, we demonstrate the first putative oncometabolite in the most common form of kidney cancer and its effects on the epigenetic landscape. Our data add to the growing body of evidence demonstrating the interplay between intermediary metabolism and nucleic acid biology in cancer.

**Materials and Methods**

**Plasmids**

Expression plasmids of FLAG-tagged TET1 CD, TET1 CM, TET2 CD, TET2 CM were kindly provided by Dr. Yi Zhang through Addgene. The L2HGDH expression plasmid pcDNA3.1-L2HGDH was constructed by cloning the full-length human L2HGDH cDNA amplified from human kidney epithelial HK-2 cells into pcDNA3.1 using primers 5'-TTTGAATTCATGGTGCCAGCGCTGCGTTAT-3' and 5'-TTTGGTACCTTATAATTCAAATCTTTGTGTACCTTCATCTCAGAATC-3'.

**Cell Culture and Transfection**

All lines were acquired from ATCC except RXF-393 (NCI), HRE152 (J.A. Copland, Mayo Jacksonville) and RCC4 (P. Ratcliffe, Oxford). Cell lines were periodically tested for mycoplasma. No other authentication was performed. For transient transfection in HEK293,
cells were transfected using Lipofectamine 2000 (Invitrogen) and calcium phosphate methods for RNA interference and cDNA expression, respectively. For L2HGDH knockdown in HK-2 cells, cells were transfected with pooled siRNA reagent (Thermo Fisher) using Amaxa 4D Nucleofector 4D nucleofector (Lonza) system according to the manufacturer’s protocol. A nontargeting scramble siRNA pool was used as a negative control (Thermo Fisher).

**RNA extraction and Quantitative RT-PCR**

Total RNA was extracted with Trizol (Invitrogen) from RCC patient samples and RCC cell lines. cDNA was generated reverse using VILO RT kit (Invitrogen) and then used as template for L2HGDH Taqman expression assay probe (Applied Biosystems). Ribosomal protein (RPL0) was used to normalize data in tissue samples. For cell line analysis, \(L2HGDH\) mRNA expression level was quantified by using \(2^{-\Delta\Delta CT}\) method normalized to GAPDH. For tissues, the \(\Delta Ct\ \text{L2HGDH (Ct L2HGDH- Ct RPL0)}\) was measured for normal tissue, low L-2HG, and high L-2HG tumor. Multivariate analyses of variance (MANOVA) followed by Analysis of Variance (ANOVA) were conducted in SAS Version 9.3 to compare the expression level (\(\Delta Ct\ \text{L2HGDH}\)) between the three groups. We used SAS GLM contrast to compare the High group to the others (Normal and Low). L-2HG values were log-transformed to meet the assumptions for parametric tests.

**Quantitative 5-hydroxymethylation (5-hmC) analysis**

For DNA dot blotting, genomic DNA was denatured, serially diluted in NaOH/EDTA solution and spotted on positively charged Nylon membranes (Roche Applied Science). The membrane was crosslinked (UVP) and then blocked with 5% milk in TBST for 30 min, followed by the incubation with the anti-5-hmC antibody (Active Motif) overnight at 4° C and HRP-conjugated anti-rabbit IgG secondary antibody for 1 hr at room temperature. After washing three times with TBST, the membrane was treated with ECL and scanned. For quantitation of 5hmC, Quest 5-hmC DNA ELISA kits (Zymo Research) were used followed the manufacturer’s protocol. Briefly, anti-5-hydroxymethylcytosine polyclonal antibody was coated to the bottom of well and denatured 100
ng genomic DNA was added. To detect DNA bound to anti-5-hmC pAb, anti-DNA HRP antibody and HRP developer was applied. Greenish-blue color was analyzed in the wells by a plate reader at 405-450nm detection.

**Metabolite extraction and Chromatography/Mass Spectrometry of 2-Hydroxyglutarate (2HG)**

For GC/MS and LC/MS analysis of tissues, human kidney samples including normal and RCC were extracted and prepared for analysis as described in the Supplemental Methods and as previously described(36).

For 2HG enantiomer analysis (i.e. D- and L-2HG quantification), samples were analyzed as previously described(37). Briefly, extracts were derivatized with DATAN (diacetyl-L-tartaric acid), which permits enantiomeric analysis, followed by liquid chromatography-tandem mass spectrometry (LC-MS/MS) analysis and normalized to protein levels.

For total 2HG (D-2HG+L-2HG) measurement of samples from *in vitro* studies, cell pellets were washed in 1x PBS three times, extracted with 10% cold trichloroacetic acid (TCA) and precipitate was removed by centrifugation. TCA in the supernatant was removed by vortexing with 4 volumes of 1,1,2-trichlorotrifluoroethane (FREON)-triocylamine (Sigma) mixture and the upper aqueous layer was collected for analysis after centrifugation. Samples were analyzed by ion chromatography coupled with negative electrospray mass spectrometry (RFIC-MS) (Dionex) and 2HG was determined by selected ion monitoring (SIM 147.1). 2HG in cell extracts was quantified by using a calibration curve of 2HG and normalized to protein content. Unless otherwise noted, 2HG refers to total levels (D- + L-).

**Statistical Analysis**

Unless otherwise noted, statistical analyses were carried out using the program “R” and Microsoft excel software. Comparisons between groups for statistical significance were
performed with a two-tailed paired t-test and ANOVA. A P-value of <0.05 was considered statistically significant in all cases.
