

IN THE SPOTLIGHT

G34, Another Connection between MYCN and a Pediatric Tumor

Miller Huang and William A. Weiss

Summary: Recurrent mutations in *H3F3A* at K27 and G34 are frequent in pediatric glioblastoma, but it is unclear how these mutations promote tumorigenesis. In this issue of *Cancer Discovery*, Bjerke and colleagues identify mutations at G34 in *H3F3A* that result in elevated expression of MYCN as a potential mechanism in gliomagenesis. *Cancer Discov*; 3(5); 484–6. ©2013 AACR.

See related article by Bjerke et al., p. 512 (7).

Brain tumors represent the most common malignancy of childhood. Of these, glioblastoma (GBM) is among the most lethal, with long-term survival rates of 10%–15%. Although multiple driver mutations have been defined in adult GBM, including genes activating RTK/RAS/PI3K and IDH1/2 signaling and suppressing p53 and RB pathways, comparatively little is known about pathways that drive pediatric GBM. Within the last year, however, much attention has been brought to the role that epigenetics plays in pediatric GBM. Whole-genome and whole-exome sequencing studies independently identified recurrent mutations in the gene encoding histone 3 variant H3.3 (*H3F3A*; refs. 1, 2).

Nuclear DNA is condensed into chromatin by winding around nucleosomes. Nine histone subunits comprise each nucleosome: 2 of each core histone (H2A, H2B, H3, and H4) and one histone H1, which together are wrapped by 2 turns of DNA. Histones contribute to epigenetic regulation of the genome through myriad posttranslational modifications and substitution of different histone isoforms. Histone H3 can localize to either centromeric or chromosomal arm locations, and is encoded by at least 15 histone H3 genes. Of these, the histone H3.3 isoform mainly localizes to chromosomal arms, is not associated with DNA replication, and contributes to transcriptional regulation (3). Mutations in histone H3.3 in pediatric glioma occur at 2 distinct residues, either K27 or G34 (1, 2). Anatomically, the K27-mutant tumors arise in pontine and more rostral midline brain structures, whereas the G34-mutant tumors are typically hemispheric. Both mutations localize to the histone tail at or near K27/K36 sites accessible to posttranslational methylation and acetylation, normally associated with gene silencing and expression, respectively. In addition to *H3F3A* mutations, pediatric GBM shows frequent mutations in

the chromatin remodeling protein ATRX (31%) and tumor suppressor p53 (54%). Interestingly, all patients with mutations in *H3F3A* G34 also had *ATRX* mutations, suggesting cooperation between these proteins in the pathogenesis of pediatric GBM (1).

A genome-wide DNA methylation analysis of both adult and pediatric GBM observed that *TP53* mutations were often found with *H3F3A* mutations in pediatric GBM, reminiscent of the association between *TP53* and the epigenetic modulator *IDH1* in adult GBM (4). Histone H3.3 K27 and G34 mutations may therefore affect genome stability and global gene expression. Sturm and colleagues (4) revealed that mutations in *IDH1* and *H3F3A* were mutually exclusive, as were the K27 and G34 mutations within *H3F3A*. In fact, a clear age distribution exists among patients with *H3F3A*- or *IDH1*-mutant tumors, with *H3F3A* K27 occurring in children, *H3F3A* G34 in adolescents, and *IDH1* in young adults. The developmental gene signatures for mutations in K27 and G34 seemed distinct as well. K27 was linked with midfetal to late fetal stages of the striatum and thalamic development, whereas G34 was associated with early to midfetal stages in striatum and neocortex development (3, 4). Together with the anatomical bias of the mutations, these distinct spatiotemporal expression signatures further suggest that K27 and G34 mutations arise in different cells of origin and are distinct diseases.

K27 is commonly methylated, raising the possibility that mutation alters regulation of a critical methylation site. The large number of distinct histone H3 genes and proteins would suggest that a point mutation in a single H3 gene would be unlikely to affect methylation of all histone H3 proteins. Surprisingly, in this regard, Venneti and colleagues recently described a significant decrease in H3K27me3 in GBM with *H3F3A* K27M, as compared with tumors wild-type for *H3F3A* (5). The most compelling explanation for this widespread effect on H3K27me3 methylation is that the H3K27M mutation acts as a dominant inhibitor of the K27 methylase, EZH2. Indeed, there is evidence that the H3K27M peptide can inhibit EZH2 methylase activity at nanomolar concentrations (6). Although it is unclear how decreased trimethylation of H3.3 K27 would achieve gliomagenesis, it has been proposed to affect differentiation pathways, as

expression of the neural developmental gene *FOXG1* is suppressed in the K27M tumors (1, 4).

Although G34 itself is not methylated, it is located near K36, a frequently methylated position. Sturm and colleagues (4) found that mutations at G34 also resulted in global hypomethylation of DNA particularly prominent at the ends of chromosomes. Thus, loss of DNA methylation at chromosome ends may provide insights into the association between G34 mutations and alternative lengthening of telomeres (1, 4). Similar to K27 mutations and despite the fact that DNA hypomethylation is typically associated with increased gene expression, G34 mutants downregulate the expression of differentiation genes such as *OLIG1* and *OLIG2* (4). The mechanism by which G34 mutations promote tumorigenesis, however, has yet to be elucidated.

In this issue of *Cancer Discovery*, Bjerke and colleagues (7) investigated the effect of G34 mutations in GBM and identified a potential therapeutic opportunity. Importantly, analysis of 2 independent data sets in this study validated several distinctions between K27- and G34-mutant tumors. First, G34 and K27 mutations exhibited differential gene expression patterns. Second, patients with K27 mutations had worse overall survival than G34 or *H3F3A* wild-type patients. Third, K27 mutations were observed in younger patients compared with G34 mutations. To analyze signaling pathways activated in G34 tumors,

the authors used the KNS42 pediatric GBM cell line, which harbors a G34V mutation. Consistent with the previous finding that *ATRX* mutations coincided with G34 mutants, the KNS42 line had a Q891E mutation in the *ATRX* gene.

Because of the close proximity of G34 with the K36 methylation site, the authors initially evaluated K36 methylation status in KNS42 cells, observing no differences as compared with pediatric GBM lines wild-type for *H3F3A*. This observation stands in contrast to a report that H3K36 was hypermethylated in a different pediatric GBM line harboring a G34V mutation (1). Nevertheless, Bjerke and colleagues hypothesized that mutation at G34 influenced the H3K36me3 binding profile throughout the genome. Indeed, an unbiased ChIP-Seq screen for H3K36me3 revealed differential binding at 5,130 regions representing 156 genes. Differential binding to H3K36me3 correlated with differential binding to RNA polymerase II, suggesting that expression of these 156 genes was altered. This gene set was enriched for regulators of forebrain and cortical development (e.g., *DLX6*, *FOXA1*), upregulated from embryonic and early fetal time points and downregulated by mid-late fetal development. In contrast, K27-mutant tumors exhibited a gene signature correlating with midline structures, including embryonic upper rhombic lip and early-mid fetal thalamic and cerebellar

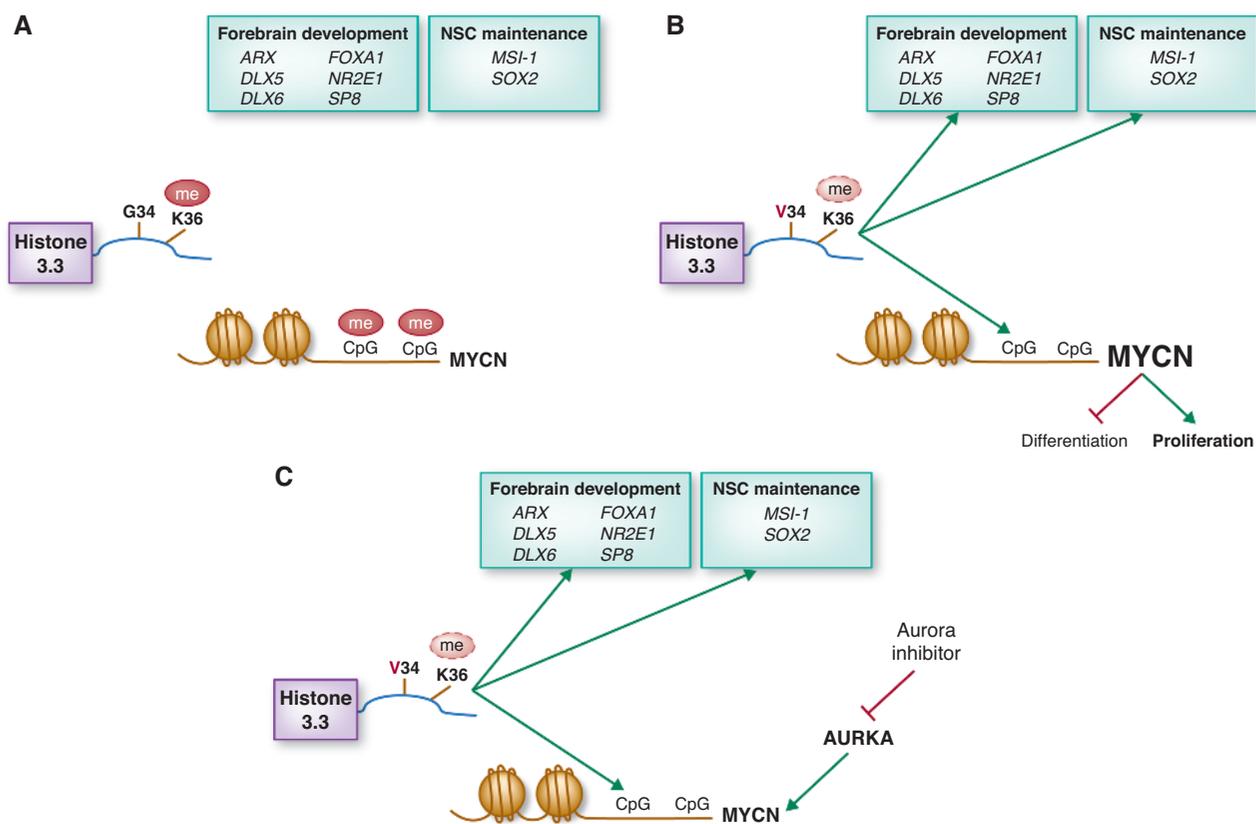

Figure 1. Targeting stabilizers of MYCN can reverse some effects of H3.3 G34 mutations in pediatric GBM. **A**, in pediatric GBM wild-type for *H3F3A*, upstream CpG islands are methylated, silencing expression of MYCN. **B**, mutation at G34 leads to hypomethylation and differential binding of H3K36 at genes implicated in forebrain development and neural stem cell maintenance. Increased expression of MYCN associated with this mutation drives proliferation and suppresses differentiation. The impact of G34 mutations on K36 methylation status remains uncertain. **C**, VX-689, a small-molecule inhibitor targeting aurora kinase A (AURKA), blocks MYCN, representing a candidate therapy for this disease.

structures, and showed maximal expression during the mid-late fetal period. These expression details further validate spatiotemporal differences between K27 and G34 mutations and provide insights into the distinct anatomical localization of G34- and K27-mutant tumors.

The most significant differentially bound gene encoded the proto-oncogene *MYCN* (~33 fold change), a gene that may alternatively be amplified in pediatric GBM, and that predicts poor overall survival in other pediatric tumors, including neuroblastoma and medulloblastoma. A general challenge in this area is the relative scarcity of GBM cell lines mutated at *IDH1/2* or *H3F3A*, and the inability, to date, to model these mutant cancers in genetically engineered mouse models. To circumvent this issue, the authors expressed mutant G34 in normal human astrocytes and transformed human fetal glial cells, observing a 2- to 3-fold induction of *MYCN* levels (Fig. 1A and B). This study implicates activation of *MYCN* as a mechanism of G34 mutation-induced tumorigenesis and should be validated in additional primary tumors and tumor-derived cell lines.

MYCN is considered undruggable, as its structure is composed almost entirely of alpha helices with no surfaces for ligand binding. Therefore, Bjerke and colleagues carried out a synthetic lethal screen to identify kinases that could represent a therapeutic target. Out of 714 kinases tested, knock-down of checkpoint kinase 1 (CHK1) or aurora kinase A (AURKA), proteins that promote *MYCN* stability, reduced viability in KNS42 cells. In a dose-dependent manner, the AURKA inhibitor VX-689 decreased levels of *MYCN* protein and cell viability (Fig. 1C). Interestingly, the bromodomain inhibitor, JQ1, was shown recently to target *MYCN*-amplified tumors by blocking *MYCN*-dependent transcription (8), suggesting BET-bromodomain inhibitors as an alternative or combinatorial approach in this tumor type.

The recent identification of *H3F3A* mutations in pediatric GBM was based on analysis of primary patient samples. How these mutations affect DNA and histone methylation and whether these effects drive tumor formation remains unclear. This article provides initial mechanistic clues into how G34 mutations influence gene expression, namely via differential binding of H3K36me3 and increased expression of *MYCN* (Fig. 1). Although the precise mechanism for how G34 mutations selectively upregulate *MYCN* expression remains to be elucidated, the elevated levels of *MYCN* in this human pediatric GBM line parallel the finding that misexpression of a stabilized allele of *MYCN* in P0 mouse forebrain neural stem and progenitor cells can generate glioma (9). Moreover, *MYCN* classically suppresses differentiation pathways, providing a potential insight into how G34-mutant tumors downregulate the expression of differentiation genes, including *OLIG1* and *OLIG2* (4). In addition to validating previous distinctions between K27- and G34-mutant tumors

and describing a molecular explanation for mutant G34-induced tumorigenesis, Bjerke and colleagues also show data that, if substantiated in additional pediatric GBM cell lines and xenografts, suggest AURKA as a relevant target for children with G34-mutant GBM.
