ABSTRACT

Somatic mutations in CREBBP occur frequently in B-cell lymphoma. Here, we show that loss of CREBBP facilitates the development of germinal center (GC)–derived lymphomas in mice. In both human and murine lymphomas, CREBBP loss-of-function resulted in focal depletion of enhancer H3K27 acetylation and aberrant transcriptional silencing of genes that regulate B-cell signaling and immune responses, including class II MHC. Mechanistically, CREBBP-regulated enhancers are counter-regulated by the BCL6 transcriptional repressor in a complex with SMRT and HDAC3, which we found to bind extensively to MHC class II loci. HDAC3 loss-of-function rescued repression of these enhancers and corresponding genes, including MHC class II, and more profoundly suppressed CREBBP-mutant lymphomas in vitro and in vivo. Hence, CREBBP loss-of-function contributes to lymphomagenesis by enabling unopposed suppression of enhancers by BCL6/SMRT/HDAC3 complexes, suggesting HDAC3-targeted therapy as a precision approach for CREBBP-mutant lymphomas.

SIGNIFICANCE: Our findings establish the tumor suppressor function of CREBBP in GC lymphomas in which CREBBP mutations disable acetylation and result in unopposed deacetylation by BCL6/SMRT/HDAC3 complexes at enhancers of B-cell signaling and immune response genes. Hence, inhibition of HDAC3 can restore the enhancer histone acetylation and may serve as a targeted therapy for CREBBP-mutant lymphomas. Cancer Discov; 7(1); 38–53. © 2016 AACR.

INTRODUCTION

Follicular lymphoma and diffuse large B-cell lymphoma (DLBCL) are the two most common subtypes of non-Hodgkin lymphoma (NHL). Although initially exhibiting an indolent phenotype, follicular lymphomas are nevertheless mostly incurable, and 40%–50% eventually transform into an aggressive and lethal form of DLBCL (1). DLBCLs manifest an aggressive and fast-growing phenotype, but can be eradicated by chemoimmunotherapy (R-CHOP) in approximately 60% of cases. Both follicular lymphoma and DLBCLs arise from B cells undergoing the germinal center (GC) reaction, a stage of the humoral immune response where B cells undergo immunoglobulin affinity maturation. GC B cells form transiently in response to T-cell–dependent antigen stimulation and are characterized by their unique ability to simultaneously proliferate and tolerate genomic instability.

These features make these cells inherently prone to malignant transformation.

Genome-sequencing studies have shown that the recurrent mutation of histone-modifying enzymes is a genetic hallmark of follicular lymphoma and DLBCL. Some of the most highly recurrent disease alleles in follicular lymphoma and DLBCL correspond to somatic mutation affecting two closely related histone acetyltransferase (HAT)–encoding genes: CREBBP and EP300. Between these two loci, CREBBP somatic mutations are more frequent, reported in 6.4%–22.3% of patients with DLBCL and 30.8%–68% of follicular lymphomas (2–7). These mutations are frequently monoallelic and tend to occur within the HAT enzymatic domain. HAT domain missense mutants may lose their ability to acetylate protein substrates, such as histones or transcription factors, due to reduced binding of acetyl-CoA (2). Mutations in EP300 occur in 5.4%–9.7% of DLBCLs and 8.7%–23.1% of follicular lymphomas (2, 3, 6, 7).

and are often mutually exclusive with those of CREBBP, suggesting that loss of either of these two genes might affect a common downstream pathway. It is not yet known how these mutations might contribute to malignant transformation. Notably, CREBBP mutations tend to be early events in lymphomagenesis, and, for example, in follicular lymphoma, likely occur in B cells that already harbor the t(14;18) translocation that drives constitutive expression of BCL2 (7).

CREBBP mediates acetylation of certain histone lysine residues, and among these the best characterized from the functional standpoint is H3K27 acetylation (H3K27ac), which is required for the activation of enhancers. Enhancers are largely responsible for cell context–specific transcriptional programming, and are located at sites distal to gene-coding regions or within introns. For a genomic region to manifest enhancer activity, it must acquire H3K4 mono/dimethylation (H3K4me1/2; ref. 8). However, for enhancers to become fully active, they require the further addition of H3K27ac mark by HATs such as CREBBP and EP300 (9). Therefore, it is possible that loss of CREBBP and EP300 activity may disrupt the activity of enhancers in B cells, and perhaps through this mechanism contributes to lymphomagenesis. Such an effect has been suggested by several recent reviews (10, 11). In this study, we explore the role and epigenetic mechanism of action of CREBBP in lymphomagenesis.

RESULTS

Crebbp Deficiency Promotes Lymphomagenesis In Vivo

Although CREBBP mutations are among the most frequent genetic lesions in NHL, their functional significance is unknown. We modeled CREBBP deficiency in VavP-Bcl2 transgenic mice, which closely recapitulate the genetics and pathology of human follicular lymphoma (12–14). VavP-Bcl2 hematopoietic progenitor cells (HPC) were transduced with GFP-encoding retroviruses (Fig. S1C). The contribution of CREBBP was evident in that only 13% to 19% of HPCs expressed GFP, whereas 90% of lymphoma cells were GFP+ (Fig. S1B). We observed a significant acceleration of lymphoma onset in VavP-Bcl2/GFP mice (n = 34, P = 0.0465) as compared with VavP-Bcl2/GFP control tumors, as determined by RNA sequencing (Supplementary Fig. S1C). This was reproduced with a second shRNA (shRNA #3, Supplementary Fig. S1E), confirming their B-cell lymphoma origin (Supplementary Fig. S1F, G, H). A similar general phenotype was observed using shRNA against Ep300 in VavP-Bcl2 transgenic mice, including the significant acceleration of lymphoma onset (n = 37, P = 0.0143, log-rank test), more aggressive histology, B-cell immunophenotype, clonality, and GC origin (Supplementary Fig. S2). Hence, CREBBP and Ep300 deficiency can promote GC lymphomagenesis and function as tumor suppressor genes.

Crebbp Deficiency Leads to Preferential Loss of H3K27ac at Enhancers

For downstream mechanistic studies exploring how loss of histone acetyl transferases could accelerate lymphomagenesis, we focused primarily on Crebbp, as (i) Crebbp KD and Ep300 KD resulted in similar phenotype, (ii) CREBBP mutations are more frequent in humans, and (iii) CREBBP mutations are mutually exclusive with EP300, suggesting overlapping mechanisms of action. To determine the impact of CREBBP loss-of-function on H3K27 acetylation pattern- ing, we performed chromatin immunoprecipitation sequencing (ChIP-seq) for H3K27ac in B220+ lymphoma cells from VavP-Bcl2/GFP mice (n = 4), as well as in VavP-Bcl2/Crebbp−/− (n = 6) mice. We identified 18,614 H3K27ac “peaks” in VavP-Bcl2/GFP lymphomas (Fig. 2A). Interestingly, there was a net loss of 3,660 (19.7%) peaks and practically zero gain of new peaks in VavP-Bcl2/Crebbp−/− lymphomas (Fig. 2A). A similar effect was observed in human GC–derived lymphoma B cells where CREBBP was depleted using two independent shRNAs, with focal loss of 13.7% of H3K27ac peaks after CREBBP knockdown (Fig. 2A; Supplementary Fig. S3A). As in the mice, depletion of CREBBP in the human cells also resulted in global reduction of H3K27ac (Supplementary Fig. S3B, C).

We focused on H3K27ac sites disproportionately affected by CREBBP loss-of-function as these would be most strongly linked to the functional impact. In human lymphoma cells, we observed that 76.9% of CREBBP-binding sites are located at putative enhancers, including introns, and distal regions (Supplementary Fig. S3C). Accordingly, we observed that H3K27ac peaks lost in VavP-Bcl2/Crebbp−/− lymphomas were disproportionately located at intergenic or intronic locations corresponding to putative enhancers (P < 2.2e−16, Fig. 2B), whereas unaffected peaks were preferentially located at promoters. Similarly, ChIP-seq studies in human cells indicated preferential loss of H3K27ac at putative enhancers (59.2% vs. 37.6% at promoters, P < 2.2e−16, Fig. 2B). Confirming this assessment, quantitative assessment of H3K27ac ChIP-seq profiles revealed increasing skewing toward enhancers among sites with progressively greater loss of H3K27ac after CREBBP loss-of-function in murine and human lymphoma cells (P < 2.2e−16; Fig. 2C–F; examples shown in Fig. 2G and H), and expression of genes near these enhancers was reduced in CREBBP-deficient cells, as determined by RNA sequencing (RNA-seq) performed in both the murine and human...
Figure 1. Crebbp deficiency accelerates B-cell lymphoma development in mice. A, Kaplan-Meier curve of C57BL/6 mice transplanted with VavP-Bcl2 HPCs transduced with MSCV-GFP retroviral vector alone (GFP, black, n = 31), or containing shRNAs against Crebbp (red, n = 34). Statistical significance of survival difference was determined by the log-rank test between shCrebbp and vector alone. B, Representative flow cytometry histograms showing the GFP-positive cell percentage of the preinjection HPCs and the splenic murine lymphoma cells that derived from the same HPCs. C, Dot plot representing the GFP-positive cell percentage in the splenic murine lymphoma cells in individual recipient animal. The mean and SEM were represented for each transplant group. Statistical significance was determined by Mann-Whitney test. D, CrebbpKD in spleen tissues extracted from recipient mice upon sacrifice. E, H&E and B220 staining of kidney and lung tissues extracted from recipient mice upon sacrifice.
CREBBP knockdown systems (Supplementary Fig. S4A and S4B). We did not observe significant correlation between gene expression reduction and promoter H3K27ac loss in mice, although there was a correlation in humans (data not shown), so that the enhancer effects were the most consistent effects of CREBBP loss-of-function. Finally, there was a significant enrichment of the murine CREBBP enhancer H3K27ac loss gene signature in human lymphoma cell enhancer H3K27ac loss genes with CREBBP knockdown (P = 6.68e–23; Fig. 2I), supporting the human relevance of the murine model. Hence, CREBBP loss-of-function preferentially affects H3K27 acetylation at enhancers and affects similar genes in humans and mice.

CREBBP Loss-of-Function Represses Enhancers that Are Poised in GC B cells

To determine more precisely how CREBBP loss-of-function perturbs enhancer function, we next mapped the location of enhancers in primary human GC B cells, which are the cell-of-origin of DLBCL and follicular lymphoma. To identify the enhancers relevant and specific to this cell type, we performed replicate ChIP-seq for H3K4me2, H3K4me3, and H3K27ac in purified primary human naïve B cells (NBC) and GC B cells. We identified 7,577 active enhancer H3K4me2/H3K4me3/H3K27ac peaks in NBCs and 5,219 in GC B cells (Supplementary Fig. S5A), the great majority (two-thirds) of which were unique and specific to each cell type. Changes in enhancer activation state were accompanied by corresponding changes in gene expression (Supplementary Fig. S5B and S5C; examples are shown in Supplementary Fig. S5D). Notably, among sites that lose H3K27 acetylation after CREBBP knockdown in mouse and human lymphomas, there was a significant enrichment for genes that also lose enhancer activity in GC B cells (Fig. 2I). Hence, CREBBP loss-of-function strengthens the repression of B-cell enhancers that are deactivated in GCs. This could contribute to lymphomagenesis by aberrantly maintaining the aspects of the GC phenotype. Indeed, further analysis of CREBBP expression (Supplementary Fig. S5B and S5C; examples are shown in Supplementary Fig. S5D). Notably, among sites that lose H3K27 acetylation after CREBBP knockdown in mouse and human lymphomas, there was a significant enrichment for genes that also lose enhancer activity in GC B cells (Fig. 2I). Hence, CREBBP loss-of-function strengthens the repression of B-cell enhancers that are deactivated in GCs. in NBCs, suggesting that BCL6 normally attenuates the MHC II locus during the GC reaction (Fig. 2j). H3K27ac at these enhancers was also reduced by CREBBP KD (Fig. 2j; Supplementary Fig. S8). These results indicate novel and opposing functions for BCL6/SMRT complexes and CREBBP in immune recognition.

**CREBBP-Mutant Lymphomas Exhibit a GC/BCL6 Target Enhancer Repression Signature**

To determine the relevance of these experimental CREBBP signatures to those occurring in the human disease, we next performed RNA-seq and mutation profiling in the DNA of two cohorts of patients with follicular lymphoma (Supplementary Table S3). Nonsynonymous CREBBP cSNVs were detected in 38.5% of cohort 1 and 46.1% in cohort 2, mostly clustering to four hotspots in the HAT domain (Supplementary Fig. S9A and S9B; Supplementary Table S4). Somatic mutations were validated by Sanger sequencing in a random subset of tumors and their germline controls (Supplementary Fig. S9C). RNA-seq was also performed in 347 DLBCL patient samples, of which 20.5% (n = 71) carried CREBBP mutations that were determined by targeted sequencing of tumor DNA (Supplementary Fig. S9A). CREBBP mutations were significantly more frequent in GCB–DLBCL than ABC–DLBCL (P = 1.42E-5, cell-of-origin classification determined by NanoString Lymph2Cx (16); Supplementary Fig. S9D) and again preferentially involved the HAT domain (Supplementary Table S5). We examined differential gene expression between CREBBP-mutant and CREBBP WT samples lacking other epigenetic mutations that might introduce confounding effects. In all three cohorts, there was a significant skewing toward the genes being more repressed than activated in CREBBP-mutant patients when we examined the top differentially expressed genes (Fig. 3a–c; Supplementary Fig. S10A). Comparison of the signatures of the three cohorts indicated that they were extremely similar [gene-set enrichment analysis (GSEA) FDR q < 0.05], confirming that similar genes were affected across patients with CREBBP-mutant follicular lymphoma and DLBCL (Supplementary Fig. S10B). The same repressive pattern was induced by CREBBP knockdown in human GC-derived DLBCL cell lines (Fig. 3d). Indeed, GSEA also revealed that the follicular lymphoma and DLBCL CREBBP mutant repressed signatures were also highly similar to the murine VavP-Bcl2/CrebbpKD lymphomas and human CREBBP knockdown cell lines (FDR q < 0.05, Fig. 3e), demonstrating that these models properly reflect the biology of the human disease, and are furthermore consistent with the fact that HAT domain mutations of CREBBP in human patients are known to result in enzymatic loss-of-function (2). In accordance with this notion, genes downregulated in human CREBBP-mutant lymphomas were highly significantly enriched for genes that normally lose enhancer H3K27ac in GC B cells, GC exit genes including CD40-induced, IRF4-induced, plasma cell differentiation, and MHC class II antigen processing and presentation (Fig. 3f; for a complete list of enriched pathways, please check Supplementary Table S2). Again, there was significant enrichment for genes with enhancers regulated by BCL6/SMRT complexes, genes induced by BCL6 siRNA, and the genes that are direct targets of EP300 and CREBBP in DLBCL cells (Fig. 3f). These results identify a conserved signature of CREBBP and BCL6/SMRT–regulated genes that control GC exit and immune recognition.

**CREBBP-Mutant Lymphoma Cells are Preferentially Dependent on HDAC3**

In normal GC B cells, induction of BCL6 results in the recruitment of the SMRT corepresor and its close homolog NCOR to enhancers, both of which in turn recruit HDAC3. The histone deacetylase HDAC3 is a component of SMRT/NCOR complexes and mediates H3K27 deacetylation of enhancers by BCL6 (17). Thus, BCL6–SMRT/NCOR–HDAC3 complexes “toggle” enhancers that are active in mature B cells likely due to EP300 and CREBBP HAT activity (based on the above data), to a poised H3K27 deacetylated configuration resulting in reduced gene expression (17). This enhancer-repressive effect is reversed when B cells exit the GC reaction through posttranslational modification of SMRT and NCOR and downregulation of BCL6, which results in reacquisition of histone acetylation (18–20). Hence, we hypothesized that a major mechanism through which CREBBP mutation/loss-of-function leads to lymphomagenesis is by partially disabling dynamic reversal of enhancer repression mediated by BCL6–SMRT/NCOR–HDAC3 complexes (Fig. 4a).

CREBBP Mechanism in Lymphomagenesis

It is well established that BCL6 maintains the growth of lymphoma cells partly through its recruitment of SMRT/HDAC3 complexes (17). Given that our data suggest that CREBBP loss-of-function particularly strengthens this aspect of BCL6 function, we postulated that CREBBP loss-of-function results in gene expression repression signature. Given that our data suggest that lymphoma cells partly through its recruitment of SMRT/HDAC3 complexes (17). Given that our data suggest that CREBBP loss-of-function particularly strengthens this aspect of BCL6 function, we postulated that CREBBP loss-of-function results in gene expression repression signature.

**Figure 3.** CREBBP loss-of-function results in gene expression repression signature. A–D, Supervised analysis of the top 500 most differentially expressed genes between CREBBP WT (CREBBPWT) and mutant (CREBBPMUT) follicular lymphoma (FL; A and B), DLBCL patients (C), or between scramble and CREBBP knockdown MD901 cells (D). Columns represent individual samples, rows correspond to the genes. Heat map represents the z-scores of the expression value (RPKM) characterized by RNA-seq. The column on the right represents the proportion of the genes that were repressed (green) or upregulated (red) in CREBBPWT patient samples as compared with CREBBPMUT patient samples (A–C), or in CREBBP knockdown cells as compared with scramble control samples of the respective cohorts (D). Statistical significance was determined by Fisher exact test. E, Summary of the GSEA of the downregulated genes in the top 500 most differentially expressed genes of respective cohorts as compared with ranked gene expression changes between either murine VavP-Bcl2/CrebbpKO and VavP-Bcl2/EV murine tumors (purple bars) or between CREBBP-KD and Scr MD901 cells (orange bars). *, significant enrichment (FDR q < 0.05). Heat map represents the −log10 BH-adjusted P value of each gene set tested.

The proliferation of CREBBP-mutant (OZ and RIVA), but not CREBBP WT DLBCL cells (Fig. 4). HDAC3 knockdown also caused more apoptosis in CREBBP-mutant RIVA cells, but not WT cell lines (Fig. 4K; Supplementary Fig. S12C). We next evaluated the effect of HDAC3 knockdown in CREBBP-mutant and WT DLBCL in vivo. We performed this experiment in two ways. First, we enriched the CREBBP-mutant (FARAGE) and WT (OCI-Ly7) cells transduced with control shRNA or shHDAC3 with a puromycin selection mark, and implanted these cells into SCID mice. We observed that knockdown of HDAC3...
impaired engraftment of CREBBP-mutant but not CREBBP WT DLBCL cell lines, as compared with control (Fig. 4L and M). Among engrafted mice, HDAC3 knockdown resulted in much more significant retardation of tumor growth in the CREBBP-mutant (P = 0.005) than WT DLBCL (Fig. 4N–Q). Immunohistochemical analysis showed a trend toward increased necrotic areas in the CREBBP-mutant mice with HDAC3 knockdown, but no difference in the CREBBP WT lymphomas (Supplementary Fig. S12D). Second, we implanted NSG mice with CREBBP-mutant RIVa cells containing a mixed population of GFP-shHDAC3 or control shRNA transduced with nontransduced cells. Five weeks after implantation, the mice were sacrificed and lymphomas evaluated to ascertain the percentage of GFP+ cells. HDAC3 knockdown lymphomas featured almost complete loss of GFP representing a highly significant depletion of GFP+ cells as opposed to control shRNA-transduced cells (P < 0.0001, Fig. 4R). Hence, CREBBP-mutant DLBCLs are addicted to HDAC3 for their proliferation and survival.

Repression of Antigen Processing and Presentation Genes Due to CREBBP Loss Can Be Rescued by HDAC3 Inhibition

Finally, to confirm the opposing actions and potential novel biological effects of CREBBP and HDAC3, we examined in greater detail their counter-regulatory effects at the MHC class II loci, which, as shown above, are counter-regulated by CREBBP and BCL6/SMRT/HDAC3 complexes. First, to confirm that the recruitment of HDAC3 to these loci was dependent on BCL6, we performed HDAC3 ChIP-qPCR in DLBCL cells after transduction with shBCL6 or control siRNA. BCL6 siRNA, but not control, induced the expected reduction in BCL6, as well as loss of enrichment of HDAC3 at MHC class II-related loci (Supplementary Fig. S13). Next, we observed that the transduction of CREBBP WT DLBCL cells (OCI-Ly7 and MD901) with either of the two CREBBP shRNAs induced significant reduction in the transcript abundance of MHC class II genes in these cells (Fig. 5A and B; for primer sequences, see Supplementary Table S6). Furthermore, this gene expression reduction was accompanied by loss of H3K27ac at enhancers of the MHC class II genes (Fig. 5C and D; for primer sequences, see Supplementary Table S6). CREBBP knockdown likewise accordingly induced significant reduction of cell surface HLA-DR as detected by flow cytometry in two independent experiments (Fig. 5E–H; Supplementary Fig. S14A and S14B). Notably, the treatment of CREBBP knockdown cells with a selective HDAC3 inhibitor (22) rescued the expression of most of these MHC class II genes (Fig. 5A and B) and H3K27ac enrichment at their enhancers (Fig. 5C and D), and restored the expression of cell surface HLA-DR (Fig. 5E–H; Supplementary Fig. S14A and S14B). Consistent with the results from Green and colleagues showing that primary CREBBP-mutant DLBCLs less efficiently induced allogeneic T-cell activation (7), we showed that CREBBP knockdown cells failed to stimulate human T-cell proliferation to the same extent as control knockdown cells (Fig. S1 and J; Supplementary Fig. S14C). This loss of the T-cell stimulation ability was at least partially rescued by treatment with the selective HDAC3 inhibitor in both cell lines (Fig. S1 and J; Supplementary Fig. S14C). Taken together, our data suggest that in GC B cells, MHC class II gene expression is controlled by enhancer toggling through BCL6/SMRT/HDAC3 complexes in contraposition with CREBBP. CREBBP mutation or loss-of-function allows greater BCL6/SMRT/HDAC3–mediated repression, resulting in the reduction of surface expression of these genes and thus potentially impairing the ability of T cells to suppress the outgrowth of malignant B cells.

DISCUSSION

CREBBP is one of the most frequently mutated genes in human lymphomas, and our study demonstrates its tumor suppressor action and provides insight into its mechanism. We find that CREBBP loss-of-function disrupts a finely tuned mechanism of enhancer toggling that controls gene expression during the GC reaction. Specifically, CREBBP and likely EP300 maintain H3K27 acetylation of specific enhancers required for the terminal differentiation and immune signaling in mature B cells. This enables B cells to undergo plasma cell differentiation upon immunization. However a subset of B cells follows an alternative fate and instead enters the proliferative and mutagenic GC reaction. In GC B cells, these enhancers are transiently repressed by BCL6/SMRT/HDAC3 complexes through H3K27 deacetylation. This effect is terminated through CD40 signaling that disrupts BCL6/SMRT repression complexes upon GC exit, upon which enhancers recover their H3K27-acetylated active state (18–20).
**Figure 5.** CREBBP regulates antigen processing and presentation gene enhancers. **A and B,** Bar plots representing the relative expression of antigen presentation and MHC II genes in OCI-Ly18 (A) and MD901 (B) cells upon CREBBP depletion and treated with either a selective HDAC3 inhibitor (HDAC3i; 20 μmol/L) or a control compound (Ctrl), as compared with scramble shRNA–induced cells (set as 1, dotted lines). Bar graph represents mean ± SEM from three replicates. **C and D,** Bar plots representing the relative H3K27ac enrichment at enhancers of MHC II genes in OCI-Ly18 (C) and MD901 (D) cells upon CREBBP depletion and treated with either a selective HDAC3 inhibitor (HDAC3i; 20 μmol/L) or a control compound (Ctrl), as compared with scramble shRNA–induced cells (set as 1, dotted lines). Bar graph represents mean and SEM from three replicates. **E and F,** Quantification of HLA-DR measured by flow cytometry in shCREBBP or scramble-transduced lymphoma MD901 (E) and OCI-Ly18 (F) cells treated with either a selective HDAC3 inhibitor (HDAC3i; 20 μmol/L) or a control compound (Ctrl). Cells were transduced with shRNAs for 3 days and then treated with compounds for 96 hours. The data was represented as mean ± SD. Statistical significance was determined by Student t test. *, significant difference between control compound-treated scramble or shCREBBP–transduced cells (P < 0.05); #, significant difference between control compound and selective HDAC3 inhibitor–treated cells (P < 0.05). **G and H,** Representative flow cytometry histograms showing cell surface level of MHC II molecule HLA-DR that were quantified in E and F. **I and J,** Bar plots showing the relative proliferation of T cells stimulated by shCREBBP or scramble-transduced lymphoma MD901 (I) or OCI-Ly18 (J) cells treated with either a selective HDAC3 inhibitor (HDAC3i; 20 μmol/L) or a control compound (Ctrl). The data indicate relative fold changes of T-cell proliferation, represented as a ratio of fluorescence (560 nm/590 nm) from each treatment to that from scramble shRNA–transduced cells treated with control compound (set as 1, dotted lines). Statistical significance was determined by Student t test.
However, CREBBP mutation results in a failure to reactivate these enhancers, which impairs GC exit and immune recognition programs, and ultimately promotes malignant transformation. Because GC enhancer deacetylation is driven by HDAC3, CREBBP-mutant lymphomas become especially dependent on this protein, as observed in our functional assays in vitro and in vivo. Hence HDAC3 dependency is an exploitable target in patients with lymphoma with CREBBP somatic mutations. Because follicular lymphomas and DLBCLs are dependent on BCL6 regardless of CREBBP mutation status, it is expected that CREBBP WT lymphomas would manifest some degree of HDAC3 dependency as well. Accordingly, our data show that HDAC3 knockdown still has mild deleterious effects in CREBBP WT DLBCL cell lines in vitro and in vivo.

Mutant CREBBP–induced loss of enhancer function is reminiscent of recent findings indicating that somatic mutations of the histone methyltransferase KMT2D in B-cell lymphomas induce malignant transformation by disrupting enhancer H3K4 monomethylation and dimethylation (14, 23). In the case of KMT2D, the impact of loss-of-function alleles is to attenuate enhancer response to CD40 and other signaling pathways. Hence, induction of gene expression linked to GC exit signals is dampened and there is aberrant persistence of GCs beyond their usual transient time frame, and affected B cells manifest a defect in class switch recombination (14). Even though KMT2D and CREBBP are both enhancer regulators, they seem to have at least partially distinct functions given that (i) somatic mutation of these two genes often occurs together in DLBCL and follicular lymphoma and (ii) their target genes and downstream biological effects are not identical [e.g., enhanced proliferation in KMT2D (14, 23) or reduced MHC class II expression in CREBBP loss-of-function].

It is important to underline that the transcriptional and epigenetic signatures induced by CREBBP knockdown in mice and human cells were highly similar to that of human patients with CREBBP mutations. Moreover, the critical mechanistic point of HDAC3 dependency was observed in both CREBBP-mutant DLBCL cells as well as CREBBP loss-of-function experiments. Finally, the loss of MHC class II gene expression and loss of the ability of lymphomas to stimulate a T-cell response was similar in CREBBP knockdown as well as CREBBP-mutant primary patients compared with respective controls (7). These three points confirm the relevance of our findings to the natural process of CREBBP somatic mutation. We underline that MHC class II loss-of-function is an important event in lymphomas, associated with inferior clinical outcome (24). Along these lines, it is notable that the BCL6/SMRT/HDAC3/CREBBP mechanism regulates not only enhancers within the MHC class II loci, but also genes that themselves play important roles in supporting MHC class II expression such as CIITA, or that enable activity of MHC class II surface proteins such as CD74. In addition to being a target gene of BCL6 and CREBBP, CIITA itself is mutated in approximately 10% of DLBCLs based on publicly available data from The Cancer Genome Atlas (data not shown), and even more frequently in primary mediastinal large B-cell lymphoma (25). The occurrence of somatic mutations of CREBBP and its downstream target CIITA in DLBCLs supports the notion that loss-of-function of antigen-presenting functions is an important aspect of lymphomagenesis. Yet we do not rule out that CREBBP mutation might have additional functions. For example, it was proposed that CREBBP mutation could impair p53 function and enhance BCL6 through reduced acetylation (2). Although the most pronounced loss of H3K27 acetylation occurred at enhancers, we point out that at least part of the function of CREBBP may still be related to effects on promoter function as shown in Supplementary Table S2. Future studies should help to determine whether any other putative effects of CREBBP are relevant to lymphomagenesis beyond those described in this article.

Finally, it is intriguing that the CREBBP–HDAC3 enhancer toggling mechanism controls expression of antigen processing and presentation genes, which could potentially disrupt immune surveillance by T cells. As noted, CREBBP-mutant lymphomas feature less T-cell infiltration and impaired ability to activate T cells ex vivo (7). We show that CREBBP loss-of-function indeed directly mediates loss of MHC class II expression and the ability of T cells to recognize B cells. Most strikingly, we show that this effect is rescued by targeting HDAC3. This finding is consistent with and refines the notion that targeting pan-HDAC inhibitors could induce MHC class II expression in lymphoma cells (26). Hence, our findings have direct ramifications for lymphoma therapy, as CREBBP-mutant lymphomas may exhibit continued requirement for HDAC3 activity to hide from T cells through epigenetic silencing of MHC class II. Synthetic HDAC3 dependence in CREBBP-mutant tumors may thus have dual actions on both immune surveillance and other growth-promoting functions of BCL6/SMRT complexes. These mechanisms indicate an opportunity for HDAC3-specific inhibitors as a precision medicine approach for CREBBP-mutant lymphomas.

**METHODS**

**Characterization of Human NHL Samples**

Characterization of NHL samples, including two cohorts of follicular lymphoma samples and one cohort of newly diagnosed DLBCL samples, was previously described by Ortega-Molina and colleagues (14). These studies were approved by either the Institutional Review Board (IRB) at Weill Cornell Medical College (WCMC; IRB#0107000499), or the Research Ethics Board at the University of British Columbia, British Columbia Cancer Agency (REB#H13-01478). Informed consent was obtained from all the subjects.

**Tonsilar B-cell Isolation**

Primary cells were isolated from normal fresh deidentified human tonsillectomy specimens (IRB#0805009767). Naïve B cells were labeled with anti-IgD-FITC followed by anti-FITC Microbeads (MACS). GC B cells were first labeled with anti-CD77 (rat IgM), then mouse anti-rat IgM, IgG1 isotype, and followed with rat anti-mouse IgG1 Microbeads. Bead-labeled cells were then enriched by passing through an autoMACS instrument using the PosselD protocol. The purity of the isolated cells is normally greater than 90%.

**Generation of Mice**

Animal studies have been approved by Institutional Animal Care and Use Committees at Memorial Sloan Kettering Cancer Center (protocol #: 07-01-002) and WCMC (protocol #: 2011-0034). The vavP-ΔB2Z mouse model of follicular lymphoma (27) was adapted to the adoptive transfer approach using retrovirally transduced HPCs (28). Briefly, vavP-ΔB2Z transgenic HPCs from fetal livers (E14.5) were transduced with retroviruses expressing short hairpin RNAs against Cebbp or empty vector.
and the recipients were monitored for 200 days. Eight- to 10-week-old C57BL/6 females were used for all transplantation experiments.

The retroviral vectors are based on MSCV (29). Mouse shRNAs were designed using Designer of Small Interfering RNA. shCrebpp #1: ATGCATCAGATTTGTGTTCTA

shCrebpp #2: CAGGACCTACGGAGTCTACCTA

shCrebpp #3: CTGGTTGCCCTATGCTAAGAAA

shEp300 #1: CAGGTCACAGGAAGATAAA

**Mouse B220+ Tumor Sample Preparation**

B220+ cells were purified from mouse lymphomas by immunomagnetic enrichment with CD45R microbeads (Miltenyi Biotec).

**Histology**

Tissues were fixed overnight in formalin, embedded in paraffin blocks, and sectioned. Tissue sections were stained with hematoxylin/eosin, B220, CD3, Ki67, and TUNEL following standard procedures.

**Histologic Score System**

Semi-quantitative scale of organ infiltration was used on the basis of the size of the infiltrate of atypical lymphocytes, corresponding to 1+ (size of the infiltrate <50% of 40x field); 2+ (size of the infiltrate >50% of 40x and <100% of 40x field); 3+ (size of the infiltrate >100x field) for all organs, except spleen. Splenic infiltrate was evaluated on the basis of the size of the white pulp and atypical lymphocytes outside of the white pulp, as follows: 1+ atypical lymphocytes occupying <60% of spleen surface; 2+ atypical lymphocytes occupying between 60% and 80% of spleen surface; 3+ atypical lymphocytes occupying >80% of spleen surface.

**Flow Cytometric Analysis**

Mouse tumor cell suspensions were stained as described previously (28). The antibodies used were B220/CD45R (BD Biosciences, 553409, 1:200), IgD (BD Biosciences, 558597, 1:200), GL7 with APC, CD19 (BD Biosciences, 557399, 1:200), IgM (BD Biosciences, 553409, 1:200), IgG (BD Biosciences, 558597, 1:200), GL7 (BD Biosciences, 561530, 1:200) conjugated with phycoerythrin, and analyzed with BD LSRFortessa cell analyzer. Analysis was performed with FlowJo software (Tree Star).

**IgVH Rearrangement Analysis**

PCR to evaluate IgVH rearrangements was performed on the cDNA of lymphoma cells with a set of forward primers that anneal to the framework region of the most abundantly used IgVH gene and the recipients were monitored for 200 days. Eight- to 10-week-old C57BL/6 females were used for all transplantation experiments.

The genomic sequences from VH to the intron downstream of JH4 were PCR-amplified from cDNA of B220+ cells using degenerate forward primers for the different VH families (31) and a reverse primer (5'-AGGCTCTGTCTGCCCTAGACAG-3'; ref. 32) downstream JH4. Proofreading polymerase (Phusion High Fidelity, NEB) was used for amplification with PCR conditions previously published (31). Amplification products were isolated from agarose gel and cloned into pGEMT, and single colonies were submitted to Sanger sequencing. Sequences were compared with IgBLAST (33).

**Cell Culture**

Human DLBCL cell lines were grown in medium containing either 1% HEPES, 1% glutamine, and 1% penicillin/streptomycin. OCI-Ly1, OCI-Ly7, and OCI-Ly18 were obtained from Ontario Cancer Institute in June 2011. FARAGE was obtained from the ATCC in May 2011. MD901 was provided by Jose Angel Martinez-Climent (Centre for Applied Medical Research (CIMA), Pamplona, Spain) in June 2011. OCI-Ly1, OCI-Ly7, OCI-Ly18, FARAGE, and MD901 were recently authenticated by Biosynthesis using their STR Profiling and Comparison Analysis Service in February 2015. RIVA and OZ were authenticated by immunophenotyping in October 2016. These cell lines have also been routinely tested for *Mycoplasma* contamination in the laboratory.

**Immunoblot Analysis**

The protein levels of CREBBP and HDAC3 in whole-cell extracts were detected by Western blotting using rabbit anti-CREBBP (Santa Cruz Biotechnology, sc-369, 1 μg/mL) and rabbit anti-HDAC3 (Santa Cruz Biotechnology, sc-11417, 1 μg/mL), respectively. Levels of H3K27ac were detected by Western blotting using histone extracts collected using the acid extraction method and blotted with rabbit anti-H3K27ac (Abcam, ab4729, 1 μg/mL) and rabbit anti-total H3 (Abcam, ab1791, 1 μg/mL).

**Knockdown of Human CREBBP and HDAC3**

The shRNA sequences used to knock down CREBBP or HDAC3 expression in human cell lines are as follows: shRNAs against human CREBBP:

shCREBBP-1: GTAACTCTGGCCTAGCTTAA

shCREBBP-2: GATGCACTGAGTTGCTTCT

shRNA against human HDAC3 used in xenograft experiment

shHDAC3-GFP1 or Puro1 (same backbone but with different selection markers):

CCGGCAAGAGTCTTAATGCGCTCTTAACCTCGAGTTAGAA

TAACTCTTTTGCTTTTGCTTTTG

shHDAC3-GFP2:

CCGGCCGCAACTGTGCTTACTTATCCTCGAGTTAACTGTAC

CATGTGCAAGGCTTTTGCTTTTG

Inducible shRNAs against human HDAC3 used in cell proliferation and apoptosis experiments:

shHDAC3-1:

TGCTGTTGACAGTGAGCGAACCATGACAATGA

CGTCTTATATGAGCAACAGAGTGTAGAAGAGCTTCTTC

GAAACCCCTTGCTACTGCTCGGA

shHDAC3-2:

TGCTGTTGACAGTGAGCGAACTGCAATGAGA

CAAGAAGCAGTGAAGCGGCAAGACAGATGTATCTCTTGACTGTGTA

CATGGTCTGCCTACTCGGA

**mRNA-seq Library Preparation and Sequencing Analysis**

Total RNA was extracted from patient samples using TRIzol (LifeTechnologies). RNA concentration was determined using Qubit (LifeTechnologies) and integrity was verified using Agilent 2100 Bioanalyzer (Agilent Technologies). High quality total RNA (100-200 ng) from each sample was subjected to sequencing library preparation following the protocols of either the Illumina TruSeq RNA Kit (human cohort 1) or the TruSeq Stranded Total RNA with Ribo-Zero (human cohort 2, mouse tumors, and MD901 CREBBP KD). Libraries were multiplexed (6 samples per lane) and sequenced on Illumina HiSeq 2500 as either 50-bp single-read runs (TruSeq RNA Kit) or the TruSeq Stranded Total RNA with Ribo-Zero (human cohort 2, mouse tumors, and MD901 CREBBP KD). Libraries were multiplexed (6 samples per lane) and sequenced on Illumina HiSeq 2500 as either 50-bp single-read runs (TruSeq RNA) or 50-bp paired-end runs (Stranded Total RNA).

Reads were mapped to the reference human (hg19) or mouse (mm10) genome sequence, using Tophat2 aligner (34) with the default parameters. The mRNA expression level for each gene was represented as FPKM, called by Cufflinks (35). For downstream RNA-seq analysis, the comparison of gene expression between two groups was determined by the Student’s t test and the Benjamini–Hochberg adjusted P values.

**ChIP and ChiP-seq Library Preparation and Sequencing Analysis**

Histone ChIPs, including H3K4me1/2, H3K4me3, and H3K27ac ChiPs in human tonsillar naïve and GC B cells, human DLBCL cell
lines, and mouse splenic tumor cells, were performed as described previously (14). BCL6 and HDAC3 ChIP-qPCR as well as BCL6 and SMRT ChIP-seq data were adapted from hazit and colleagues (17). Briefly, 1–5 × 10^6 cells were fixed with 1% formaldehyde for 10 minutes at room temperature, followed by nuclei preparation and sonication (Branson Sonicator). Antibody (CREBBP, Santa Cruz) for 45 minutes at room temperature, performed as described previously (17) with modifications. Briefly, 2–10^6 cells were fixed first with 2 mmol/L of disuccinimidyl glutarate (DSG, ProteoChem, C1104) for 45 minutes at room temperature, followed by 1% formaldehyde for 10 minutes at room temperature. Fragmentation of fixed chromatin was performed by sonication of nuclei (Branson Sonicator) to achieve enrichment of short fragment chromatin (100–500 bp). Antibody [1–2 μg; H3K4me1/2, Abcam, ab32356; H3K4me3, Abcam, ab8580; H3K27ac, Abcam, ab4729, all tested using histone-peptide array (Active Motif 13001) for specificity] was added to precleared chromatin lysate and incubated overnight at 4°C. Enriched chromatin was collected by protein-A beads (Roche) pull-down and subsequent reverse cross-linking and purification. ChIP-seq libraries were prepared from 5–10 ng ChIP DNA following instructions of Illumina TruSeq ChIP Sample Prep Kit. Pooled libraries (6 samples per lane) were then sequenced on Illumina HiSeq 2500 as 50-bp single-end runs.

CREBBP and EP300 ChIP-seq in DLBCL cell line OCI-Ly7 was performed as described previously (17) with modifications. Briefly, 2 × 10^6 cells were fixed first with 2 mmol/L of disuccinimidyl glutarate (DSG, ProteoChem, C1104) for 45 minutes at room temperature, followed by 1% formaldehyde for 10 minutes at room temperature. Fragmentation of fixed chromatin was performed by sonication of nuclei (Branson Sonicator) to achieve enrichment of short fragment chromatin (100–500 bp). Antibody (CREBBP, Santa Cruz Biotechnology, sc-360; EP300, Santa Cruz Biotechnology, sc-584; 5 μg conjugated with Dynabeads protein A (Thermo Fisher Scientific) was added to precleared chromatin lysate and incubated overnight at 4°C. Enriched chromatin was isolated through extensive wash steps and subsequent reverse cross-linking and purification. ChIP-seq libraries were prepared from 5–10 ng ChIP DNA following the instructions of Illumina TruSeq ChIP Sample Prep Kit. Libraries were then sequenced on Illumina HiSeq 2500 as 50-bp single-end runs.

Single-end reads were mapped to the reference human (hg18) or mouse (mm10) genome, using BWA aligner (36) with the default parameters. Only reads mapping uniquely to the genome with not more than 2 mismatches were retained for downstream analysis. Peak detection in each sample was performed with the ChIPseeker program (37) and annotated to genes and/or promoters based on hg18 or mm10 refseq genes.

The consensus peaks from mouse H3K27ac ChIP-seq for the normal and tumor samples were defined by the overlapping peaks which appear in ≥3 of the 4 normal samples, and ≥4 of the 6 tumors samples (shCrebbp), respectively. The consensus peaks from MD901 H3K27ac ChIP-seq for the scramble shRNA (control) and shCREBBP samples were defined by the overlapping peaks which appear in ≥2 of the 3 samples for the control, and 4 of 6 samples for shCREBBP (i.e., 2/3 samples for both shRNA, or 3/3 samples for one shRNA and 1/3 samples for the other shRNA), respectively.

**Pathway Analysis**

The pathway analysis was performed as published previously (38). Briefly, the gene sets for canonical pathways and Gene Ontology (GO) terms were downloaded from the Molecular Signatures Database (MSigDB; ref. 39) using C5 collection. The B-cell and lymphoid-specific signatures were curated by Staudt laboratory (downloaded from ref. 40) or Melnick laboratory from previous publications. This database contains approximately 250 gene sets/signatures associated with normal lymphoid biology and lymphoid neoplasms. For the complete list of pathways, please check Supplementary Table S1.

**Gene-Set Enrichment Analysis**

All the GSEA results in this article were generated from GSEA preranked mode (39). The input files are all the genes and their gene expression level logFC (log2 fold-change) from each RNA-seq data set, including (i) the three follicular lymphoma or DLBCL patient cohorts (CREBBP mutation vs. WT), and (ii) the shRNA data for the mouse or human MD901 cell line (shCrebbp vs. scramble shRNA). All the gene sets used in GSEA were curated by the Staudt laboratory (40) or Melnick laboratory from previous publications.

**Mutation Discovery**

Exome sequencing of cohort 1 using Agilent SureSelect (Human All Exome 50 Mb Target Enrichment System for Illumina Paired-End Sequencing Library Kit (Agilent Technologies), Ra inning targeted resequencing of cohort 2 (RainDance Technologies), targeted resequencing of cohort 3 (347 tumor samples and 67 matched normal samples), cell-of-origin calling of cohort 3 by Lymph2Cx 20-gene GEP assay on the NanoString platform (NanoString Technologies), as well as mutational calling algorithms were described previously in Ortega-Molina and colleagues (14). Agilent Exome and Raindace platforms were cross-validated using DNA from DLBCL cell lines. More than 95% concordance was observed. Cohort 3 DLBCL targeted resequencing results were further validated by the Fluidigm Access Array system (Fluidigm Corporation).

**NS-DAD Animal and Experiment**

NS-DAD mice were a generous gift from Dr. Mitchell Lazar (21). Age- and sex-matched mice were immunized intraperitoneally with 0.5 ml of a 2% sheep red blood cell (SRBC) suspension in PBS (Cocalico Biologicals) and sacrificed after 10 days. For staining of GC B-cell populations, single-cell suspensions from mouse spleens were stained using the following fluorescent-labeled anti-mouse antibodies: PE-Cy7-conjugated anti-B220, APC-conjugated anti-B220, PE-conjugated anti-FAS, and APC-conjugated anti-CD38. DAPI was used for the exclusion of dead cells.

**Cell Proliferation Assay**

After DLBCL cell lines transduced with inducible shRNAs against Luciferase gene (Lac, control) and human HDAC3 (shHDAC3-1, shHDAC3-2) were treated with 0.2 μg/ml doxycycline for 24 hours, cells were labeled with 2.5 μmol/L Cell Proliferation Dye eFluor 670 (eBioscience, 65-0840) and cultured for additional 5 days. The fluorescence intensity of the dye (APC channel) in the GFP- (FITC channel) cells was measured by flow cytometry right after labeling and every 24 hours subsequently until the end of the experiment.

**DLBCL Xenotransplant Models**

Ten million puromycin-selected, scramble, or HDAC3 shRNA-transduced human DLBCL cells (FARAGE or OCI-Ly7) were subcutaneously injected in the left flank of 8-week-old SCID mice. Tumor volume was monitored every 3–4 days using electronic digital calipers (Thermo Fisher Scientific) in two dimensions when tumors became palpable. Mice were sacrificed by cervical dislocation under anesthesia at the end of the experiment when tumors in the scramble shRNA group reached maximum size allowed by the animal protocol. Fifteen million of either scramble or HDAC3 shRNA-transduced human DLBCL RIVA cells were subcutaneously injected in the flank of 8-week-old NSG mice. The shRNA vector in this experiment contains a GFP marker. The GFP+ cell percentage before injection was measured by flow cytometry. Tumor volume was monitored every 3–4 days using electronic digital calipers in two dimensions when they became palpable. Mice were sacrificed by cervical dislocation under anesthesia at the end of the experiment when tumors in the scramble shRNA group reached maximum size allowed by the animal protocol. Single-cell suspension was prepared from individual tumor and stained with anti-human CD19-PE (BD Biosciences, 555413) and DAPI to determine the percentage of GFP+ cells in the CD19-positive human B-cell population by flow cytometry.
siRNA Transfections

OCI-Ly1 cells were transfected using Nucleofector 96-well Shuttle system (Lonza) with 1 μmol/L siRNA against BCL6 (HSS100968) or nontargeted siRNA (46-4001, Stealth RNAi, Invitrogen).

Mixed Lymphocyte Reaction

MD901 and OCI-Ly18 B-lymphoblastoid cell lines (BLCL) were transduced with scramble or CREBBP-shRNAs for 3 days and then treated with a selective HDAC3 inhibitor (20 μmol/L) or a control compound for 96 hours. BLCLs were irradiated (9,000 r 131 Cs) and added to 1.5 × 10^6 CD3+ T cells at a ratio of 10:1 T-BLCL in triplicate flat-bottom microwells. Cells were incubated for 5 days at 37°C 5% CO2, after which T-cell proliferation was assessed by CellTiter Blue Assay (Promega G8081).

Statistical Analysis

Sample sizes for comparisons between cell types or between mouse genotypes followed Mead’s recommendations (42). Samples were allocated to their experimental groups according to their predetermined type (i.e., mouse genotype) and, therefore, there was no randomization. Investigators were not blinded to the experimental groups unless indicated. In the case in Fig. 1A, only mice that developed lymphomas were censored; mice that did not develop lymphomas were considered censored and included with ticks in the Kaplan-Meier curves. Survival in mouse experiments was represented with Kaplan-Meier curves, and significance was estimated with the log-rank test. For contingency analysis, we used the χ² exact test.

Data Deposition

The RNA-seq and Chip-seq data are available at the Gene Expression Omnibus database (SuperSeries: GSE79686; MD901 H3K27ac Chip-seq: GSE79639; MD901 RNA-seq: GSE79684; mouse H3K27ac Chip-seq: GSE79640; mouse RNA-seq: GSE79685).
