Running title: HPV 16/18 vaccine efficacy in Guanacaste

Word count: 4109, 1 figure, 8 tables, 9 supplemental tables

Keywords: clinical trial, HPV vaccine, Guanacaste, age, cross-protection
Funding/Support and Financial Disclosures

The Costa Rican Vaccine Trial is a longstanding collaboration between investigators in Costa Rica and NCI. The trial is sponsored and funded by NCI (N01-CP-11005) with support from the NIH Office of Research on Women’s Health and conducted in agreement with the Ministry of Health of Costa Rica. The NCI and Costa Rica investigators are responsible for the design and conduct of the study; collection, management, analysis, and interpretation of the data; and preparation of the manuscript. Vaccine was provided for our trial by GSK Biologicals, under a Clinical Trials Agreement with NCI. GSK also provided support for aspects of the trial associated with regulatory submission needs of the company under FDA BB-IND 7920. Douglas Lowy and John Schiller are named inventors on U.S. government owned HPV vaccine patents that are licensed to GSK and Merck, and so are entitled to limited royalties as specified by federal law. None of the other co-authors have any potential conflicts of interest to report.
Abstract

Target groups for HPV vaccination are controversial. We evaluated vaccine efficacy (VE) against 1-year persistent infection, stratified by age and sexual behavior. We randomized 7,466 healthy women 18-25y to HPV16/18 or Hepatitis A vaccine (follow-up=50.4 months). According-to-protocol (ATP) cohorts included compliant HPV-negative women; intention-to-treat (ITT) included all randomized women. ATP VE was 90.9% (95%CI=82.0, 95.9) against HPV16/18 infections, 44.5% against HPV31/33/45 (95%CI=17.5, 63.1) and 12.4% (95% CI=-3.2, 25.6) against any oncogenic infection. Overall ITT VE against HPV16/18 infections was 49.0%, but ATP and ITT VE almost reached 100% in year 4 of follow-up. ATP efficacy against HPV16/18 was similar by age, but ITT VE was highest among youngest women (68.9% among 18-19; 21.8% among 24-25 years olds) and 79.8% among virgins. Among previously unexposed women, vaccination is highly efficacious against HPV16/18 and partially against HPV31/33/45. Vaccination is most effective before initiating sexual activity, with programmatic and individual decision implications.
Statement of significance

In an independent trial of the bivalent ASO4-adjuvanted HPV 16/18 vaccine (Cervarix) conducted among young women in Costa Rica, we confirmed the high efficacy against HPV 16/18 persistent infection and partial cross-protection against HPV 31/33/45. Furthermore, efficacy data suggests that the benefit of HPV vaccination is maximal when the vaccine is given to young women before initiation of sexual activity.
Introduction

HPV vaccines have enormous potential for cervical cancer (CC) control, and developed countries are vaccinating adolescent girls to prevent cervical neoplasia. However, the worldwide CC burden (500,000 cases annually) will only decline with high vaccination coverage in developing countries, where most cases (85%) occur (1). In this context, target ages and population groups to maximize reduction in morbidity, treatment and mortality are still controversial.

The two vaccines based on L1-virus-like-particles licensed worldwide, quadrivalent Gardasil® (2,3) and bivalent Cervarix®, (4,5) are highly protective against cervical neoplasia caused by vaccine HPV types 16 and 18 among women without current or past infection with these types. There is also evidence of limited cross-protection against HPV31, 33, 45 and possibly others (5-7). However, vaccination does not increase clearance or decrease progression of established infections (8,9).

The ultimate goal is CC prevention, but trials with that endpoint are impractical. The choice of trial endpoints has been intensively debated (10). Regulatory authorities required histopathological outcomes, namely cervical intraepithelial neoplasia grade 2 or greater (CIN2+) (in effect mainly CIN2), as cancer surrogates in licensure trials.

Although HPV infection is a necessary cause of CC, acute infection is extremely common and usually clears within months (11). Persistent oncogenic HPV infection, which is less frequent, is a much better endpoint than incident infection and, in some respects, a better
surrogate marker than CIN2, because infection can be measured with high reproducibility (12), while CIN2 is subject to significant histologic misclassification (13). Also, attribution of the HPV type that caused a CIN2+ is difficult when multiple-type infections are present, as is common (14).

Evaluating vaccine efficacy and potential impact in population subgroups can assure maximum benefit from high-cost programs in different settings. Developing countries with limited resources are considering whether investment in this preventive measure is worthwhile. In developed countries, benefit is uncertain for older women born in earlier cohorts and those who miss vaccination as adolescents, particularly in the US, where vaccine uptake in adolescents is limited (15).

We report here on efficacy of an HPV16/18 ASO4-adjuvanted vaccine (Cervarix®, Glaxo SmithKline Biologicals) in a large community-based clinical trial in a high incidence area of Costa Rica (16), with 1 year persistence of a cervical HPV infection as endpoint, including estimates of vaccine efficacy by age, sexual behavior and previous exposure to individual HPV types. We present results for both ITT cohorts, reflecting real world efficacy, and ATP cohorts, as a proxy for an ideal where women are fully vaccinated before exposure, so they can receive maximum benefit.
Results

Figure 1 presents the CONSORT diagram. Of nearly 25,000 women screened, 7,466 women were randomized, with 3,727 in the vaccine arm and 3,739 in the control arm (ITT cohort for HPV 16/18). The ATP cohort comprised 2,635 and 2,677 women in the vaccine and control arm, respectively. The 7,466 women represented 59.1% of 12,624 potentially eligible women (considering those with recruitment deferred beyond the enrollment period for different reasons as non-eligible) and 30.5% of all 24,467 women screened from the census.

Age, study clinic, presence and number of individual HPV types detected and baseline cytology were similar in the two arms (Supplemental Table 1). As noted before (8), HPV16 was more common at baseline in vaccine than control arm (6.0% vs. 7.1%, p=0.05). For this analysis, women in the ATP cohort for HPV 16/18 had accumulated 10,268 and 10,472 person years in the vaccine and control arm, respectively, with a median follow-up time of 50.4 months. Total follow-up time, number of visits, maximum time between tests, and number of annual, semi-annual or colposcopy visits were similar by arm (data not shown). More than 90% of eligible women attended their corresponding visits and provided specimens.

Estimated vaccine efficacy against HPV16/18 was 90.9% (95%CI=82.0, 95.9) in the ATP cohort and 49.0% (95%CI=38.1, 58.1) in the ITT cohort (Table 1). The efficacy against HPV31/33/45, for which previous evidence of protection exists, was 44.5% (95%CI= 17.5, 63.1) in the ATP cohort. Efficacies against other oncogenic types combined were not significant. The overall efficacy against all oncogenic types was approximately 10% in
both the ATP and ITT analyses. Considering individual A9-species HPV types in ATP cohorts, protection against target HPV16 was 86.5% (95%CI=72.9, 94.0), with significant cross-protection against HPV31 (45.7%, 95%CI=8.2, 68.6). There was a non-significant cross-protection (37.3%, 95%CI=-51.4, 75.3) against HPV33, but not against other types in this species (Supplemental Table 2). In A7-species, efficacy against HPV18 persistent infection was 100% (95%CI=90.7, 100.0), with non-significant cross protection for closely related HPV 45 (52.0%, 95%CI=-9.8, 80.4). The other types in this species had non-significant negative estimates of efficacy. In species A5 and A6, the only noteworthy finding was an increase in persistent infection with HPV 51 (A5) in the HPV arm (VE: -63.9% (95%CI=-150.7, -8.2).

Table 2 presents ATP efficacy against HPV 16 by baseline HPV 16 serology status. Rates of ‘breakthrough’ persistent infections in the HPV arm were higher among seropositives than seronegatives, even though in the control arm, the rate of infections was lower in the seropositives. Thus, efficacy was over 90% among HPV16 seronegative women, but only 50% among the seropositives. Interestingly, efficacy against HPV16 was similar among HPV18 seronegative and seropositive women.

Efficacy in the ATP cohort was similar regardless of vaccination age (p for trend 0.362 (Table 3); however, in the ITT cohort, VE declined from 68.9% (95%CI=53.1, 79.9) for women 18-19 years old to 21.8% (95% CI=-16.9, 47.9) among 24-25 years olds (p for trend=0.005). Corresponding rate reductions per 100 women vaccinated declined from 5.2 (95% CI=3.6, 6.6) to 1.6 (95% CI=-1.0, 4.0). Similarly, in the ITT cohort, efficacy was highest among virgins at enrollment (79.8%, 95%CI= 44.9, 94.1), with decreasing efficacy
with increasing time since first sexual intercourse (Table 4) and increasing number of
sexual partners (Table 5). When considering stratification of the ITT results by time since
first sexual intercourse and number of sexual partners, virgins, despite high vaccine
efficacy, had a lower rate reduction than sexually active women, because they can only
contribute outcomes after initiation of sexual activity and therefore have less observation
time. Among sexually active women, rate reductions, like vaccine efficacy, declined with
time since first sexual intercourse. On the other hand, rate reductions increased with the
number of sexual partners despite declining vaccine efficacy, as a consequence of the
higher attack rate with increasing number of partners.

We also investigated VE according to time between vaccination and incidence of
persistent infections (Table 6). In the ATP analysis, VE against HPV 16/18 increased with
time since enrollment to 100% after 34 months. In the ITT analysis, efficacy also
increased with follow-up from only 16% in the first two years to over 90% after 46 months.
A similar effect was observed when considering efficacy against HPV 31, 33 and 45
combined, with ATP efficacy going from 41.7% (95%CI=-31.3, 75.4) 10-22 months after
vaccination to 57.6% (95%CI=-31.9, 88.5) after 46 months. In the ITT analysis,
corresponding VE went from -19.4% (95%CI= -64.9, 13.3) to 53.1% (95%CI=8.0, 77.1).

In an effort to compare the VE to prevent 12-month persistent infections with VE to
prevent 6-month persistent infections, we also calculated VE against that outcome,
including the same stratified analyses (Supplemental tables 3-9). The results were very
similar although there is more statistical power. In this context, it is noteworthy that HPV
31 was no longer the only non-vaccine HPV type with significant protection. The VE to prevent 6-month infection with HPV 45 was 73.0% (95% CI = 45.3, 87.8).

Among women who were HPV DNA positive at enrollment, we did not detect significant efficacy against persistent infection with any of the HPV types investigated (supplemental table 10).

We also analyzed the 600 subjects excluded from ATP because they received at least one of the 3 vaccine doses outside the ATP windows. Estimates of VE against HPV16/18 using similar exclusion criteria as those for the ATP analysis and among all women (ITT) produced results similar to the respective analyses among women who received their 3 doses within the windows (supplemental table 11).

**Discussion**

Results from this independent trial support the strong protective effect of Cervarix against 12-month HPV16/18 persistent infections in the ATP cohort (5). Protection was close to 90% against these two types which are responsible for about 70% of cervical cancers (17). In addition, we observed nearly 50% cross protection against HPV 31/33/45, associated with about 10% of cancers. The VE against HPV16/18 was only 50% when considering all vaccinated women (ITT), and just 12% when considering persistent infections with any oncogenic HPV type, even in ATP cohorts.
For these analyses, we chose the surrogate outcome of persistent infection, which is highly reproducible (18), unlike histopathologic endpoints emphasized in previous reports. In previous work we have reported from Guanacaste, we compared the relative reproducibility and validity of CIN2 and CIN3 diagnoses by comparing community pathologists’ diagnoses with 2 independent reviewers from the United States (total, n = 357). Two review pathologists agreed with 84% and 81%, respectively, of initial diagnoses of CIN3 compared with 13% and 31% of CIN2. Although CIN3 is a substantially more reproducible diagnosis than CIN2, the latter constitutes an important fraction of lesions in reported clinical trials (13). In addition, the virologic outcome provides direct assessment of causality in the presence of multiple infections and has a relatively high positive predictive value for subsequent development of lesions (19). The ITT analyses incorporate the reality of incomplete vaccination in mostly sexually active adults, and can be extrapolated to other populations of similar age, sexual behavior and compliance. In contrast, most women in the ATP analyses are probably naïve to HPV infection, allowing extrapolation to women vaccinated before sexual debut and who comply with vaccination regimens.

We observed statistically significant cross-protection against HPV31/33/45 as a group. There was no apparent efficacy against the very common persistent infections with HPV types other than HPV16, 18, 31, 33, and 45, an association that attenuated the overall efficacy against persistent infections with all oncogenic types down to 12%. The nominally significant deleterious effect on HPV51 may be a chance finding among many comparisons made, and was not observed in the other large Cervarix trials (20). The 4-year follow up of our study was too short to see whether other HPV types replace vaccine
types in vaccinated cohorts. Natural history data do not indicate that one HPV type modifies the epidemiology of the other (21,22), but we did not investigate whether the presence of a non-vaccine type modifies the vaccine’s protection against infection with HPV16 or HPV18.

Inclusion of women regardless of serostatus, which is imperfectly measured, allowed us to observe the full impact of the vaccine in a population including presumably immune women. The ATP VE against HPV16 among women seronegative for HPV16 was 92.2%, about twice as high as in seropositives. The attack rate of persistent infection was lower in seropositives than seronegatives in the control arm, likely reflecting natural protection by serum antibodies and possibly other immune mechanisms (23), or reduced exposure a few years after initiation of sexual activity. The higher attack rate of persistent infection among seropositives than seronegatives in the vaccine arm may reflect high proportions of missed infections (possibly due to inadequate sampling of the genital tract, missed test results or latent infections) in women who do not benefit from vaccination because they were infected before baseline. The absence of reduction in efficacy against HPV16 persistent infection among HPV18 seropositives suggests that immune protection, rather than other correlates of sexual activity associated with antibody levels, explains the effect.

Similar efficacy against persistent infection with HPV16/18 in ATP analysis by age indicates that the vaccine is effective at protecting against new infections in unexposed women independent of age. The strong decline in efficacy from 68% at ages 18-19 to 21% at ages 24-25 in the ITT cohort probably reflects that in the latter, there is a significantly larger fraction of women who have initiated sexual activity prior to vaccination.
and have been exposed to HPV. Rate reductions also clearly decline with age and years since first intercourse, with the exception of virgins who do not contribute time at risk until they start sexual activity. It should be noted however, that the reduction in vaccine efficacy and rate reductions is only present in the age group 24-25. Interestingly, rate reductions tend to be higher among women with more partners (as their attack rate is higher) despite lower vaccine efficacy. These results indicate that both susceptibility and rates of transmission are important parameters when assessing the potential impact of prophylactic vaccines and have implications for vaccination efforts and screening policy. In the absence of a test to determine expected benefit of an individual woman, age appears to be clearly a criterion to consider for definition of target groups for vaccination. The declines in estimates of VE seen with increasing age and time since sexual debut suggest that many infections that could eventually progress to cancer occur early, and can only be prevented with adolescent vaccination.

The observation that vaccination did not substantially reduce oncogenic infections has implications for screening programs, because the positive predictive value of the tests will likely be reduced, as many of the persistent infections by non-vaccine HPV types are unlikely to progress to significant lesions. The lack of reduction in infections with the lesser oncogenic types can lead to more diagnostic and therapeutic procedures than necessary in vaccinated cohorts.

Interestingly, we noted that VE against HPV 16 and HPV 18 tended to increase with time since vaccination, to 100% in the ATP cohort and to almost 95% in the ITT cohort, with a similar effect for the combined outcome of HPV 31, 33 and 45 (to a maximum close to
60%). One possible explanation of increasing efficacy against persistent HPV16/18 infections with time since vaccination in the ATP cohort is waning influence of false-negative baseline HPV DNA results, for which efficacy is zero or low. This interpretation is supported by the reduced VE against HPV 16 observed among women who were seropositive for anti-HPV 16 antibodies. Similarly, the likely explanation in the ITT cohort is waning influence of baseline prevalent infections. In ITT, increased VE with time since vaccination reflects protection against new infections, but the impact of this protection in the out years needs to be interpreted in the context of the fact that exposure tends to be higher early on after initiation of sexual activity, with reduced exposure typically seen with increasing age/time.

Most of the findings, including the stratified analyses were similar using a 6-month HPV persistence endpoint, with the advantage that the number of endpoints was larger, indicating that 6-month persistence could serve as an adequate surrogate endpoint in HPV vaccine trials, particularly for the evaluation of HPV types that occur with lower frequency or have lower vaccine efficacies that require larger sample sizes to achieve statistical significance. In this study, for example, VE against HPV 45 was not significant using the 12-month endpoint but was clearly so with the 6-month endpoint.

This analysis has some limitations and strengths. One of the limitations is that we had a relatively small sample size to accurately assess the lower efficacy of individual non-vaccine HPV types, as has been the case with other clinical trials of Cervarix (5). Those multicentric trials as well as those reported for Gardasil recruited smaller number of women in multiple research centers. In contrast, the Costa Rica HPV trial was conducted
in a homogeneous population of young women at high risk of HPV infection. In this context, the results can be extrapolated to similar groups of women in areas of high HPV prevalence. It should be noted however, that high prevalence of HPV in young women is very common in most areas of the world, particularly those where the vaccine is been considered to control the cervical cancer problem. Differences in sexual practices, in particular the distribution of age at first intercourse in the population should be taken into account when designing HPV vaccination programs. One of the strengths of this study is that it is a large trial in a stable community, which will allow long term follow-up up of these cohorts. Moreover, the fact that the results of this trial are very similar to those obtained in the multicentric trials points to the generalizability of vaccine efficacy results. The fact that participation rates at enrollment were limited could also affect the external validity of the results, but not the internal validity of the randomized trial. We used virological outcomes, which have some advantages as they are highly reproducible and do not present problems for causality assessment in the presence of multiple infections. However, the clinical significance of virological outcomes, particularly for non vaccine types is still under active debate.

In conclusion, the clear benefit of Cervarix against persistent HPV16/18 infections observed among unexposed women decreases with age and sexual experience. These findings, together with extensive data indicating that HPV is acquired early on after sexual debut (24,25) and the possibility of natural immunity (23) suggest limited value, in general, for vaccination beyond a few years after adolescence in areas of high prevalence of HPV infection and high risk of cervical cancer. Efforts that focus vaccination on women before sexual debut may be most effective at reaching the most vulnerable groups.
**Materials and Methods**

Design, subjects and procedures

This analysis presents a double-blind randomized controlled trial of Cervarix among healthy women 18-25 years old. Detailed methods have been published (16).

Potential participants from a census were invited (June 2004-December 2005). After signing informed consent, an interview, medical history, physical exam and pregnancy test were conducted. For eligibility, women had to be healthy, not pregnant, not breastfeeding and using contraception during the vaccination period. Main exclusion criteria were chronic diseases, history of reactions to vaccines, and history of hepatitis A or vaccination against it. Women were recruited and randomized regardless of past sexual behavior, HPV status or cytology.

A pelvic exam was performed on sexually experienced women. Exfoliated cells for cytology, HPV DNA, CT DNA, GC DNA and other testing were collected with a Cervex brush by firmly rotating the brush 5 times 360° around the cervical os. In women whose cervix exhibited extensive ectopy, the cervex brushing was also used on the ectocervix to insure sampling of the squamo-columnar junction. Blood was collected from all participants (16).

Randomization and vaccines
Participants were randomized with equal chance to Cervarix® or Hepatitis A vaccine. Each dose of the HPV16/18 vaccine contained HPV16 and HPV18 L1 virus-like-particle (20 μg of each) adjuvanted with 50 μg 3-O-desacyl-4′-monophosphoryl lipid A and 0.5 mg aluminum hydroxide. Each dose of the control hepatitis A vaccine contained 720 ELISA units (EU) of inactivated hepatitis A antigen and 0.5 mg aluminum hydroxide. Both were formulated in 0.5 ml doses with identical packaging and appearance to assure blinding. Vaccination schedule consisted of 3 doses at 0, 1 and 6 months. Desirable windows for vaccination defined periods beyond which the corresponding dose was not administered (16). At 6 months, sexually active women self-collected vaginal cells for HPV testing, with results comparable to clinician-collected specimens (8).

Follow-up

Each participant was scheduled for 4 annual follow-up examinations. Cytology was classified using the Bethesda system (26). Women with LSIL or HPV positive ASC-US were followed semi-annually for safety until obtaining 3 normal results. A repeat LSIL, HPV positive ASC-US, a single ASC-H, HSIL+ or glandular abnormalities prompted colposcopy and treatment as needed. Unsatisfactory cytology was managed as LSIL.

The study was approved and supervised by the IRBs of the Instituto Costarricense de Investigación y Enseñanza en Nutrición y Salud (INCIENSA) in Costa Rica and the NCI in the US.

Safety monitoring
All participants were observed 30-60 minutes following vaccination. Adverse event and pregnancy information was actively collected during follow-up. An independent data and safety monitoring board (DSMB) met regularly to examine unblinded adverse event (most recent meeting February, 2011), and repeatedly recommended trial continuation. The study is still blinded and investigators had no access to unmasked data by arm; therefore, no safety data are presented in this report. However, two published reports on pregnancies and autoimmune conditions have included safety data from this study (27,28).

HPV DNA and antibody testing

Broad spectrum PCR-based HPV DNA testing was performed at DDL Diagnostic Laboratory, based on amplification and probe hybridization using the SPF$_{10}$ HPV DNA enzyme immunoassay (DEIA) system followed by typing using the LiPA$_{25}$ version 1 line detection system as described (29,30). To ensure that HPV16 and HPV18 infections were not missed, all specimens positive for HPV DNA using SPF$_{10}$ DEIA but negative for HPV16 or HPV18 by LiPA$_{25}$ were also tested with type-specific primers/probes for the presence of HPV16 and HPV18 DNA (30,31).

ELISA was used for the detection and quantification of IgG antibodies against HPV16 and 18 separately by GSK as described (32).

Statistical analysis
Results presented are post-licensure analyses, conducted by an external group (Information Management Systems, IMS) under the direction of the investigators, who remain masked to individuals’ randomizations.

We defined persistence as detection of same-type HPV in samples collected at two visits, at least 10 months apart (minimum required for two consecutive annual visits), without intervening negatives. Similarly, 6-months persistence was calculated as detection of same-type HPV in samples collected at two visits, at least 4 months apart (minimum required for two consecutive semi-annual visits). There were a total of 2,668 oncogenic infections with 10+ months between first detection and last detection, of which 496 (18.6%) are not counted as persistent due to intervening negatives.

We defined different cohorts for each endpoint of HPV infection. According-to-protocol (ATP) cohorts include women who received 3 doses within protocol-defined windows, were protocol-compliant during vaccination, had no biopsy/treatment before the 6 months visit, and were HPV DNA-negative by PCR for the corresponding HPV type at enrollment and the 6-month visit (when receiving third dose) (2,635 women in the HPV vaccine arm and 2,677 in the control arm) (16). The intention-to-treat (ITT) cohorts include all randomized women, regardless of compliance or enrollment infection (3,727 in the HPV arm and 3,739 in the control arm).
Balance by arm overall and within subgroups was evaluated by exact binomial test when the number of women was ≤30 and by the analogous normal approximation to the binomial test when the total was >30.

Vaccine efficacy (VE) is the percentage reduction in endpoint related to vaccine administration, estimated as the complement of the ratio of the cumulative attack rates (AR) in the HPV and control arms. The AR is the percentage of women in the cohort who experience the endpoint. The confidence interval for VE is derived from the corresponding confidence interval for the risk ratio. The exact conditional test was used for analyses of VE. The analytical unit for all analyses is the woman rather than the infection because our principal interest is to determine the proportion of women protected against persistent HPV infections with the potential to cause cancer in the woman.

We used the difference between the ARs in the vaccinated and control arms to address the question of absolute impact of vaccination overall and in subgroups. The confidence interval for the difference was calculated based on the exact test.

The primary objective in our pre-specified plan was to evaluate VE against 1-year persistent infection with HPV16 and/or HPV18 (HPV 16/18). We evaluated cross-protection against HPV31/33/45, for individual oncogenic HPV types, and for all oncogenic types combined. 6-month persistent infection was also evaluated in secondary analyses. In addition, stratified VE was calculated by enrollment covariates (age, age at first intercourse, time since first intercourse, number of sexual partners, HPV DNA and antibody status).
Oncogenic HPV types include HPV 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66 and 68-73 (68-73 cannot be differentiated with genotyping method employed). PCR results from all visits of a participant were included in the analyses (annual, semi-annual and colposcopy).

More than 600 women received their 3 doses outside the strict ATP windows. Separate cohorts were defined to analyze efficacy in this subgroup using similar criteria for ATP and ITT as described above.

Our results are based on an event-triggered statistical analysis plan (SAP) approved by US FDA. The SAP specifies a one-sided $\alpha$-level of 0.001 for this "interim" analysis of persistent HPV-16/18 infections. Results in this paper provide the most up-to-date available data from the latest data freeze of 21 June 2010. A previously published abstract for the International Papillomavirus Conference (IPC) held in July 2010 included analysis of persistent HPV-16/18 infections from an earlier (1 Jan 2010) data freeze; the P-value was $<10^{-10}$ in the ATP cohort. For regulatory purposes, we consider that the two freezes constitute two separate interim analyses, leaving 0.023 (=0.025-0.001*2) as the one-sided $\alpha$ level when we perform our final analysis. Only the analysis of persistent HPV-16/18 infections entails $\alpha$ spending according to the SAP. Other analyses are exploratory in the SAP and do not require adjustment.

Acknowledgements

We would like to extend a special thanks to the women of Guanacaste and Puntarenas, Costa Rica, who gave of themselves in participating in this effort. We also acknowledge
the tremendous effort and dedication of the staff in Costa Rica involved in this project, including Bernardo Blanco and his team (census), Ricardo Cerdas and Ana Hernández (blood processing), José Miguel González, Osman López, Johnny Matamoros, Manuel Sánchez, Rafael Thompson and Jorge Umaña (field activity coordinators), Su Yen Araya, Hazel Alvarez, Hayleen Campos, Muriel Grijalba, Ana Cristina Monge, Ana Peraza, Diana Robles, María Fernanda Sáenz, Dorita Vargas, and Jessica Vindas (clinic coordinators), Paola Alvarez, Dinia Angulo, Ana Live Arias, Betzaida Barrantes, Andrea Bolaños, Diego Bonilla, Marianela Bonilla, Mary José Calvo, Loretto Carvajal, Jessenia Chinchilla, Blanca Cruz, Marianela Herrera, Andrea Interiano, Fabiola Jiménez, Erick Lagos, Viviana Loría, Andrea Messeguer, Rebeca Ocampo, Ana Cristina Ocampo, Silvia Padilla, Angie Ramírez, Daniela Romero, Byron Romero, Yessenia Ruiz, Daniela Ruiz, Genie Saborío, Sofía Soto, Malena Salas, Adriana Torrez, Natalia Ugalde, Adriana Vallejos, Yesenia Vásquez, Maricela Villegas (clinicians), Marta Alvarado, Ana Cristina Arroyo, Gloriana Barrientos, Diana Díaz, Marlen Jara, Maureen Matarrita, María Ester Molina, Elida Ordóñez, Adriana Ramírez, Gina Sánchez, and Sihara Villegas (nurses), Arianne Castrillo and Vivian López (education and outreach effort coordinators), Karla Coronado (appointment coordinator), Ricardo Alfaro (quality control coordinator), Yenory Estrada (pharmacist) Charles Sánchez and Livia Romero (document center coordinators), Cristian Montero (quality assurance, regulatory) and Carlos Avila and Eric Alpízar (IT coordinators). Special recognition is also extended to Sofía Elizondo, Executive Director of Fundación INCIENSA and her staff for their administrative support. In the United States we would like to extend our appreciation to the team from Information Management Services (IMS) responsible for the development and maintenance of the data system used in the trial and who serve as the data management center for this effort. We would
like to specifically acknowledge the invaluable contributions made by Julie Buckland and Laurie Rich. We acknowledge the contributions made by individuals at Westat, Inc., who provided project development and/or monitoring support, including Maribel Gomez, Kirk Midkiff, Isabel Trejos and Susan Truitt. We acknowledge the assistance provided by Carla Chorley, Troy Moore, Kathi Shea, Mindy Collins and Heather Siefers in the establishment of a specimen and vaccine repository for our trial and in their continued assistance with the handling and shipment of specimens. From GSK Biologicals, we would like to acknowledge the contributions of Gary Dubin, Anne Schuind, Kelechi Lawrence, Darrick Fu, and Bruce Innis for their contribution to discussions regarding trial conduct and Francis Dessy and Catherine Bougelet for HPV-16/18 antibody testing. We would like to thank members of the Data and Safety Monitoring Board charged with protecting the safety and interest of participants in our trial (Steve Self, Chair, Adriana Benavides, Luis Diego Calzada, Ruth Karron, Ritu Nayar, and Nancy Roach) and members of the external Scientific HPV Working Group who have contributed to the success of our efforts over the years (Joanna Cain, Chair, Diane Davey, Francisco Fuster, Ann Gershon, Elizabeth Holly, Silvia Lara, Wasima Rida, Henriette Raventós, Luis Rosero-Bixby, and Sarah Thomas).

Cervarix is a registered trade mark of the Glaxo Smith Kline Biologicals group of companies.

Gardasil is a registered trade mark of Merck and Co. Inc.

Registered with clinicaltrials.gov: NCT00128661.

*aATP (according to protocol) cohort includes women who received all 3 doses within protocol – defined windows, complied with the protocol during the vaccination period did not have a biopsy or treatment (LEEP) prior to the 6-month visit and were HPV DNA negative (by PCR) for at least one of the HPV types in the endpoint at enrollment and at the 6-month visit.

*bITT (intention to treat) cohorts include all women randomized and vaccinated, regardless of prevalence of infection and follow-up visits.

*cOne-sided P-value for test of vaccine efficacy equals zero against the alternative that vaccine efficacy is greater than 0 is less than 10^-17.

*dOne-sided P-value for test of vaccine efficacy equals zero against the alternative that vaccine efficacy is greater than 0 is less than 10^-11.

aATP (according to protocol) cohort includes women who received all 3 doses within protocol – defined windows, complied with the protocol during the vaccination period did not have a biopsy or treatment (LEEP) prior to the 6-month visit and were HPV DNA negative (by PCR) for at least one of the HPV types in the endpoint at enrollment and at the 6-month visit.

bITT (intention to treat) cohorts include all women randomized and vaccinated, regardless of prevalence of infection and follow-up visits.

List of figure and table legends

Figure 1 legend

HPV=human papillomavirus. CIN2+=cervical intraepithelial neoplasia grade 2 or higher. LEEP=loop electrosurgical excision procedure. *Four women received discordant vaccines (one woman was enrolled twice and received three doses of each vaccine and three women received two doses of one vaccine and one dose of the other vaccine). For the aim of this analysis, the women were assigned to the group for which the first dose was given.

Table 1 legend

\(^a\)ATP (according to protocol) cohort includes women who received all 3 doses within protocol – defined windows, complied with the protocol during the vaccination period did not have a biopsy or treatment (LEEP) prior to the 6-month visit and were HPV DNA negative (by PCR) for at least one of the HPV types in the endpoint at enrollment and at the 6-month visit.

\(^b\)ITT (intention to treat) cohorts include all women randomized and vaccinated, regardless of prevalence of infection and follow-up visits.

\(^c\)One-sided P-value for test of vaccine efficacy equals zero against the alternative that vaccine efficacy is greater than 0 is less than 10\(^{-17}\).

\(^d\)One-sided P-value for test of vaccine efficacy equals zero against the alternative that vaccine efficacy is greater than 0 is less than 10\(^{-11}\).
aATP (according to protocol) cohort includes women who received all 3 doses within protocol – defined windows, complied with the protocol during the vaccination period did not have a biopsy or treatment (LEEP) prior to the 6-month visit and were HPV DNA negative (by PCR) for at least one of the HPV types in the endpoint at enrollment and at the 6-month visit. The stratification by HPV 16 serology excludes 31 and 45 subjects without HPV 16 serology results from the vaccine and control arm, respectively.

The stratification by HPV 18 serology excludes 48 and 57 subjects without HPV 18 serology from the vaccine and control arm, respectively.

bITT (intention to treat) cohorts include all women randomized and vaccinated, regardless of prevalence of infection and follow-up visits.
Table 4 legend

aATP (according to protocol) cohort includes women who received all 3 doses within protocol – defined windows, complied with the protocol during the vaccination period did not have a biopsy or treatment (LEEP) prior to the 6-month visit and were HPV DNA negative (by PCR) for at least one of the HPV types in the endpoint at enrollment and at the 6-month visit.

bITT (intention to treat) cohorts include all women randomized and vaccinated, regardless of prevalence of infection and follow-up visits.
Table 5 legend

ATP (according to protocol) cohort includes women who received all 3 doses within protocol – defined windows, complied with the protocol during the vaccination period did not have a biopsy or treatment (LEEP) prior to the 6-month visit and were HPV DNA negative (by PCR) for at least one of the HPV types in the endpoint at enrollment and at the 6-month visit.

bITT (intention to treat) cohorts include all women randomized and vaccinated, regardless of prevalence of infection and follow-up visits.

Table 6 legend

ATP (according to protocol) cohort includes women who received all 3 doses within protocol – defined windows, complied with the protocol during the vaccination period did not have a biopsy or treatment (LEEP) prior to the 6-month visit and were HPV DNA negative (by PCR) for at least one of the HPV types in the endpoint at enrollment and at the 6-month visit.

bITT (intention to treat) cohorts include all women randomized and vaccinated, regardless of prevalence of infection and follow-up visits.
Figure 1. Trial profile

24,467 Screened

17,001 Excluded
- 3,561 Ineligible (out of area)
- 2,186 Ineligible (other reasons)
- 1,527 Not located
- 5,158 Refused
- 4,569 In deferred status at end of enrollment

7,466 Women randomized *

3,727 Randomized to HPV-16/18
- 1,092 Excluded
  - 26 CIN2+
  - 17 HPV 16/18 positive
  - 28 biopsy/LEEP before V6
  - 703 <3 doses
  - 318 doses out of window or out of age range

ATP cohort
2,635 women

3,739 Randomized to control
- 1,062 Excluded
  - 22 CIN2+
  - 31 HPV 16/18 positive
  - 23 biopsy/LEEP before V6
  - 663 <3 doses
  - 323 doses out of window or out of age range

ATP cohort
2,677 women

HPV = human papillomavirus. CIN2+ = cervical intraepithelial neoplasia grade 2 or higher. LEEP = loop electrosurgical excision procedure.
